THE
TREASURY OF NATURAL HISTORY

OR

A POPULAR DICTIONARY OF ZOOLOGY

IN WHICH THE CHARACTERISTICS THAT
DISTINGUISH THE DIFFERENT CLASSES, GENERA, AND
SPECIES, ARE COMBINED WITH A VARIETY OF INTERESTING INFORMATION
ILLUSTRATIVE OF THE HABITS, INSTINCTS, AND GENERAL
ECONOMY OF THE ANIMAL KINGDOM

BY

SAMUEL MAUNDER

Author of 'The Treasury of Knowledge' 'The Scientific and Literary Treasury' &c.

SIXTH EDITION

REVISED AND CORRECTED, WITH AN EXTENDED SUPPLEMENT, BY

T. SPENCER COBBOLD, M.D. F.L.S.

Lecturer on Botany, Zoology, and Comparative Anatomy at the
Middlesex Hospital Medical College

Embellished with 900 Woodcuts expressly engraved for this work

PREFATORY NOTE

BY THE EDITOR

A SIXTH Edition of this popular Compendium of Zoological Science having been demanded, I have endeavoured to bring its information up to the present time. This has been accomplished by the introduction of corrections and emendations in the body of the work, and more particularly, by the addition of a Supplement, which had become an imperative necessity. So wide are the recent strides of Natural History Science, that in the brief interval which has elapsed since the last edition of this "Treasury" was issued, a multitude of novel and important facts have been brought to light. Among these may be here specified, in the first place, the re-discovery of that huge living, anthropomorphous ape, the Gorilla, whose position in the scale of animated nature has given origin to a most instructive controversy; secondly, further knowledge of the remarkable genetic changes, or Alternations of Generation, known to occur in many of the lower animals during their passage from the embryonic up to the adult condition; and thirdly, the great variety of extinct monsters, whose skeletal remains have been investigated by the devoted cultivators of palæontological research.

The Supplement, therefore, embracing about one hundred brief articles, will be found to contain not only a record of the above-mentioned discoveries, but also ample notices of remarkable and otherwise interesting animals, such as the Kiang, Eland, Baleniceps, Sieholdia, Euplectella, &c., the previous records of which were either imperfect or altogether wanting.

T. S. C.

INTRODUCTION.

A DICTIONARY of ANIMATED NATURE, upon a comprehensive plan, had long occupied my thoughts, before I first publicly announced my intention of making this addition to my series of popular "TREASURIES."

It will be seen at the first glance, that the whole of the articles are printed in *alphabetical* order; so that the *name* of any animal being previously known, its zoological character and its habits can be instantly ascertained; while those persons who wish to study this branch of Natural History according to the most approved modern *system* will only have to refer to this "INTRODUCTION," and they will find not only an outline of Cuvier's celebrated arrangement, as developed in the last edition of his *Règne Animal* with those alterations and additions required by the present advanced state of the science, but, under each Class and Order, references to the different genera, &c., described in the body of the Work. Thus, this CLASSIFIED INDEX will be the means of supplying the necessary *systematic* information. But whether the articles be so consulted, or merely read in a more desultory way, I believe that a vast fund of instruction and amusement will be found here collected. And so, in truth, there ought. Many of the most celebrated standard zoological works have been put under contribution, and accurate information has been gleaned from all. Nor is it among the least of the advantages which, I presume, this volume will be found to possess over most others on this subject, that, besides numerous entirely new articles, and condensed abridgements of the more elaborate writings of many acknowledged authorities, I have had an opportunity of making myself acquainted with many interesting facts now for the first time recorded in a popular digest of Animated Nature. It will also be apparent that I have not hesitated to make copious extracts from the recent Publications of various living writers who have displayed the wonders of Animated Nature under new aspects, and with increased force, originality, and beauty. In this, I have most scrupulously acknowledged the sources whence my pages have been enriched; and to the many scientific men and pleasing writers to whom I am thus indebted, I beg to return my warmest acknowledgments.

It would be easy to extend my Introductory Remarks to a considerable length by dilating on the uses and advantages to be derived from an acquaintance with Natural History; nor would it be difficult to show how much that is bright and beautiful in Nature is for ever lost to him who has never become conversant with the study. But my inclination is to avoid what some ill-natured critics might term *twaddle*, and my limits forbid me to descant on a theme which others (who are far better qualified than I can ever possibly become) have treated with all the ardent enthusiasm that is inherent in the breast of every true votary of Nature. The subject, indeed, presents a wide field for the employment of the mental faculties; and I confess it is difficult to repress some of the thoughts that arise from its contemplation. No part can be viewed as unimportant or uninteresting—none that is unworthy of the most attentive consideration, or that can fail to impress the mind with

feelings of profound admiration for the works of NATURE. Marvellous, indeed, as they are all, the most astounding manifestations of Supreme intelligence are unquestionably displayed in his character as "LORD AND GIVER OF LIFE," as the Creator and Preserver of all that "live, move, and have their being." It is therefore that portion of the "wondrous whole" which we term The ANIMAL KINGDOM that demands our especial regard, and is in the highest degree calculated to gratify a laudable curiosity, as well as to reward the labours of the most diligent research.

The Zoological descriptions are followed by a *Syllabus of PRACTICAL TAXIDEMY*. It might have succeeded as a separate publication; but the attractive nature of this volume, I trust, is likely to make it very extensively known.

As to the manner in which this work has been embellished, I can speak with perfect satisfaction. About *Nine hundred accurate Woodcuts* have been given in Mr. R. Branstons best manner, and they will no doubt be properly appreciated.

I shall now offer a *Systematic Classification* of the principal contents of this volume, a mode which, I trust, will be found at once simple and scientific, and calculated to remove any objection that might be urged against my adoption of the *alphabetical arrangement* in the body of the Work.

S. M.

THE ANIMAL KINGDOM,

THE

TREASURY OF NATURAL HISTORY;

OR, A POPULAR

Dictionary of Animated Nature.

AARD-VARK. The name by which the quadruped *Orycteropus Capensis* is known to the Dutch colonists at the Cape of Good Hope. The following cut, which is copied from Daniell's work on the Animals of

AARD-VARK (*ORYCTEROPUS CAPENSIS*)

Southern Africa, will give a good idea of its form. [For an account of its habits, see *ORYCTEROPUS*.]

AARD-WOLF. A name given by the European colonists in the neighbourhood of Algoa Bay, in South Africa, to a carnivorous digitigrade animal, which at first sight might be easily mistaken for a young striped hyæna. It is about the size of a full-grown fox, and in habits and manners somewhat resembles it. [See *PROTELES*.]

ABDOMINALES. An order of fishes in the Linnæan system, consisting of all those species which have the ventral fins placed behind the pectoral, or upon the abdomen, the cartilaginous fishes alone excepted. This arrangement has, however, been departed from by Cuvier as defective; and in its present acceptance the term *Abdominales* denotes a family or subdivision of Malacoptyergious or soft-finned fishes only, including therein the greater number of the fresh-water species, and such as periodically migrate from the ocean to deposit their spawn. As familiar instances, we may specify the Salmon and Trout.

ABERDAVINE. A small migratory Passerine bird, more generally termed the SISKIN [which see]. In Sussex it is known as the Barley-bird, because it is usually a visitant of that county about the barley seed-time.

ABOU-HANNES. An African bird, supposed to be the *Ibis religiosa*, or White Ibis, of the ancient Egyptians. [See *IBIS*.]

ABRAMIS. A genus of Malacoptyergious fishes. [See *BREAM*.]

ABRANCHIATA. An order of the *Annelida*, composed of animals having no branchial appendages. Of these, the Earth-worm and the Leech are examples.

ABROCOMA. A genus of small Rodent animals, native of South America, remarkable for the extraordinary fineness of their fur. They have large ears, small claws, and the tail rather long, and not tufted. Their general aspect is intermediate to that of the Chinchillas and Rats or Voles.

ACALEPHÆ. A group of *Cœlenterata*, comprising all those animals which float and swim in the water, by alternate contractions and dilatations of the body, although their substance is merely gelatinous, and without any apparent fibres. They are popularly named *sea-nettles*, from their causing, when touched, a disagreeable sensation, like the sting of a nettle: they are also familiarly known as *jelly-fishes*, *sea-bubbles*, &c., from the extreme softness of their tissues, which

**PURPLE OCEANIC JELLY-FISH.
(*EUREKÆA PURPURÆA*.)**

melt away, as it were, when removed from the water. Their form is circular, and there is only one opening into the body, which serves both for the mouth and vent. Although possessed of a certain degree of locomotive power, the movements of the *Acalephæ* are very feeble; and they are consequently often driven by the winds and rough currents on shore, where they are either beaten to pieces by the waves, or left dry by the tide. The *Acalephæ* are of various forms: many, indeed, are not yet thoroughly known; but the specimens which

are most commonly met with in our climate, when examined in their native element, are seen to be composed of a large mushroom-shaped gelatinous disc, from the lower surface of which various processes and filaments depend. There are, in fact, obvious points of resemblance among them all; but still they admit of division into genera and subgenera. Thus, we may observe, the genus *Medusa* includes those which have a central disc, more or less convex, on the upper surface, something like the head of a mushroom, and those that have a true mouth on the under-side of the disc; but this mouth is sometimes a simple opening, and at other times placed on a peduncle: while the genus *Eurea* includes those in which the mouth is simple, and not on a peduncle. When the disc is furnished with tentacula all round, they constitute the genus *Eurea*, the species of which are extremely abundant in tropical seas. These animals feed chiefly on Mollusca and Crustacea. [See also JELLY-FISH, p. 355; and for an account of their development, see STROBILA and ALTERNATION OF GENERATION in SUPPLEMENT.]

ACANTHOCEPHALA. An order of Entozoa, which may be exemplified by the *Echinorhynchus gigas*, often found in abundance in the alimentary canal of swine. The form of this parasite is elongated, tapering to the tail: the head consists of a retractile snout or proboscis, armed with four circles of sharp recurved spines, and it can be withdrawn or protruded at will. These singular parasites have neither mouth nor stomach, their nutriment being imbibed through the general surface of the body. Some of the species are truly formidable to look at, but, fortunately, none of them infest man. [See ECHINORHYNCHUS in SUPPLEMENT.]

ACANTHOCINUS. A genus of Coleopterous insects belonging to the *Longicorn* group. There are but few European species: the antennæ in the male are more than four times the length of the body.

ACANTHOPHIS. A genus of venomous serpents, allied to the Vipers, but distinguished from them in many essential characters. The head of the *Acanthophis* is broad and compressed, the mouth capable of great extension, and the tail is terminated by a little spur or horny excrescence, whence its name is derived. They are natives of Australia; secrete themselves in holes or beneath the roots of trees, and exhibit an astonishing tenacity of life. The *A. Brownii* is reckoned the most venomous Reptile found near Port-Jackson.

ACANTHOPODA. A tribe of Clavicorn Coleopterous insects (composed of only one genus, *Heterocerus*), distinguished by their flattened feet, which are broad, and armed on the outside with spines; the tarsi short and four-jointed with ordinary sized claws, and the body depressed; the prosternum is dilated; the antennæ are rather longer than the head, eleven-jointed, the last six forming a nearly cylindrical serrated mass.

ACANTHOPTERYGII. One of the three primary grand divisions, or natural orders, of fishes; originally recognized by our countrymen Willoughby and Ray, afterwards systematized by Artedi, and since established by Cuvier. The characteristics of the *Acanthopterygii* are, that they possess bony skeletons, with prickly spinous processes in the dorsal fins. The Stickleback and Perch are familiar examples of this division.

ACANTHURUS, or SURGEON-FISH. A genus of *Acanthopterygious* fishes, many of which are remarkable for the beauty of their

SURGEON FISH. (ACANTHURUS)

form and the variety of their colours. They are chiefly distinguished by the sharp and lancet-like moveable spines with which they are armed on each side of the tail; hence, as they cannot be handled incautiously with impunity, they have obtained from English sailors, &c., the name of "doctors." They abound in the tropical seas, but are never seen elsewhere.

ACARIDÆ. Of these small spider-like animals, M. Latreille makes four divisions: 1. Mites, (*Trombidites*); 2. Ticks, (*Ricinities*); 3. Water Mites, (*Hydrachnellæ*); and 4. Flesh Worms (*Microphthira*). Some of these exist on the ground, others in the water; some are parasitical, living on the blood and humours of the animals or insects on which they are fixed, while others insinuate themselves under the skin, where they multiply prodigiously. Of these latter, the Itch-insect (*Sarcoptes scabiei*), is a remarkable example. Their mouths are, in general, formed rather for suction than for mastication; and their extremities are commonly armed with what may be likened to a small pair of pincers. Some have four eyes, some two, and several appear to have none. The common Cheese-

ACARUS DOMESTICUS.

mite (*Acarus domesticus*) is familiar to every one. Another has the power of spinning webs, and is well known as the Red Spider, in hot-houses, where it greatly injures the plants by covering the leaves with its webs. There are also Ticks, Harvest-bugs, Water Mites, and many others, which will be noticed in their alphabetical order. We may here, however, observe, en passant, that so widely are the *Acaridæ* disseminated through animate

and inanimate objects, that it would be difficult indeed for the most patient naturalist to describe them. Myriads swarm around us: they float in our drink; over-spread our food and fruits; and if viewed with a microscopic eye, would make some loathe the choicest viands, and nauseate the most delicious productions of nature. The Mites possess great powers of life, resisting for a time the application of boiling water, and living long in alcohol.—It is a species of *Acarus* that Mr. Crosse is thought to have produced by galvanic action; but naturalists who have attended closely to such matters can readily and rationally account for their production in the usual way.

ACASTA. A genus of Cirrhipedes, found imbedded in sponges. [See *BALANUS*.]

ACCENTOR. A group of Passerine birds, many of which are peculiar to America; but including also our well-known Hedge-sparrow (*Accentor modularis*).

ACCIPITRES. The first order of birds in the Linnæan system, comprising such as have the beak or upper mandible hooked, and an angular projection on each side near the point; as the Eagles, Falcons, Hawks, and Owls. They are among birds what the *Carnivora* are among quadrupeds.

ACEPHALA. A class of Molluscs, distinguished by having no apparent head, but a mouth only, concealed in the bottom, or between the folds, of their mantle. The testaceous *Acephala* are by far the most numerous; all Bivalve shells, and some kinds of Multivalves belonging to them. [See *LAMELLIBRANCHIATA*; and for a familiar example, see *OYSTER*.]

ACERA. A name applied to a group of Apteroous insects, characterized by the absence of antennæ.

ACERÆ. A family of Gasteropodous Mollusca, distinguished by the tentacula being so much shortened, widened, and separated, that there seem to be none at all, or rather, they form together a large, fleshy, and nearly square buckler, under which the eyes are placed. They approximate in many respects to the *Aplysice*. The shell, in those which have one, is more or less convolute, without a visible spire, and the mouth has neither sinus nor canal. The genus *Bulla* belongs to this family.

ACHATINA. A genus of terrestrial Pneumonobranchous Gasteropods, popularly known by the name of *agate-snails*. They are characterized by an oval oblong shell, striated longitudinally, with the aperture ovate, and never thickened or reflected, and a smooth, straight columella, truncated at the base. All the species are oviparous; and among them are some which are the largest of all land shells. They always live near water about trees, and are very plentiful in Africa, near the Cape of Good Hope. Some are found in the West Indies; and there are two small species, *Achatina acicula* and *Achatina octona*, found in England, among the roots of trees at the base of limestone

ACHATINA VIRGINEA.

rocks. The *Achatina columnaris* is one of the most remarkable of land shells; it is reversed, and the columella forms a winding pillar, visible within, quite to the summit of the spire. Many are covered with a thick epidermis, as the *Achatina zebra*; but others are destitute.

ACHATINELLA. A small genus of shells, differing from *Achatina*, in having the inner edge of the outer lip thickened, and a slight groove near the suture of the spire.

ACHERONTIA. A genus of Lepidopterous insects belonging to the family *Sphingide*. Of this genus there are two or three species closely resembling each other: one of these is found in this country; and is known as the *DEATH'S-HEAD HAWK-MOTH* (*Acherontia atropos*). This magnificent insect varies in the expanse of its wings from four to considerably more than five inches. The upper pair are of a very dark brown colour, varied with black, especially near the base, near which is an undulated bar of pale ochre: the disc is varied with deep black

DEATH'S-HEAD HAWK-MOTH
(ACHERONTIA ATROPOS.)

undulated lines, and ferruginous patches, minutely irrorated with white, of which colour there is a central spot, and several wavy connected bars beyond the middle. The posterior wings are fulvous orange, with a narrow central and a broader dented bar running parallel with the hinder margin. The head and thorax are brownish black, the latter with a large pale, skull-like mark on the back: the abdomen is fulvous, with the incisures of the segments black, and a lead-coloured stripe runs down the back. When disturbed or irritated, this insect emits a squeaking sound. From this circumstance, as well as from the singular mark just mentioned, its appearance is regarded with much dread by the vulgar in several parts

of Europe, as ominous of some approaching calamity. The Caterpillar from which this curious insect proceeds is in the highest degree beautiful, and far surpasses in size every other in this country, measuring sometimes near five inches in length, and being of very considerable thickness. Its colour is a bright yellow; the sides being marked with seven elegant broad stripes or bands, of

CATERPILLAR OF DEATH-HEAD MOTH.

a mixed violet and sky-blue colour, which meet on the back, and are there varied with jet-black specks: on the last joint of the body is a horn or process, curving over the joint in the manner of a tail. This caterpillar is principally found on the potato and the jessamine, those plants being its favourite food. It usually changes into a chrysalis in the month of September, retiring for that purpose pretty deep under the surface of the earth; the complete insect emerging in the following June or July.

"Another peculiarity connected with the history of this Moth," Mr. Westwood observes, "consists in its attacking bee-hives, ravaging the honey, and dispersing the inhabitants. It is singular that a creature with only the advantage of size should dare, without sting or shield, singly, to attack in their strongholds these well-armed and numerous people; and still more singular, that amongst so many thousands of bees it should always contend victoriously. Huber, who first noticed the fact, asks, 'May not this moth—the dread of superstitious people—also exercise a secret influence over insects, and have the faculty, either by sound or some other means, of paralysing their courage? May not such sounds as inspire the vulgar with dread be also the dread of bees?' He also states that he was witness to the curious fact that some bees, as if expecting their enemy, had barricaded themselves by means of a thick wall of propolis and wax, completely obstructing the entrance of the hive, but penetrated by passages for one or two workers at a time; thus instructing us, that at the period when the moth appears, when also wasps and robber bees attack the hive, it is advantageous to narrow the entrances to it, so as to prevent the depredations of these obnoxious insects. The species appears to be distributed over the greater part of England and Scotland, and many specimens are annually obtained by labourers when employed in getting up potatoes."

ACHETIDÆ. A family of Orthopterous insects, ordinarily called Crickets. [See CRICKET.]

ACHEUS. A name applied by M. F. Cuvier to such of the *Tardigrada*, or Sloths, as have three claws on their fore-feet.

ACHIRUS. A genus of flat-fish, belonging to the order *Malacopterygii*; in form resembling the Sole, but distinguished from all other genera by the total want of pectoral fins; hence their name. The Achiri have no air-bladder, and consequently remain for the most part at the bottom of the sea; yet their motions are there frequently very rapid. They abound mostly in the East and West Indies; and as they keep near the shores, they furnish a plentiful supply of wholesome food to the inhabitants. The most remarkable of this species is the *Achirus marmoratus*, which has the caudal fin distinct from the anal and dorsal, all of which are of a pale bluish-white colour, thickly studded with small black spots. The flesh is of a delicate flavour, and highly esteemed. There is also another of the Achiri deserving notice, the *Achirus pavonius*, so called from the beauty of its spots, which cover the body of the fish like those on a peacock's tail.

ACIPENSER (sometimes written **ACCIPENSER**). A genus of fish in the Linnæan system, the distinguishing characteristics of which are, that the mouth is retractile and destitute of teeth, and the gills have only one aperture on each side. [See STURGEON.]

ACONTIAS. A genus of Serpents, formerly confounded with the *Angues*, or common snakes, but differing from those reptiles in certain peculiarities of osteological formation, as well as in their habits; and therefore Cuvier considered it necessary to establish this new genus. They are characterized by the absence of all the bones which represent the extremities of the other angues, while they retain the structure of the head common to those animals and the lizards, and have the body similarly covered with small scales only. The progressive movements of the Acontias are consequently very different from those of common serpents: they carry their heads and breasts erect; and, though by nature harmless and even timid, when pursued they will dart courageously at their assailant. There are few countries in the Old World in which some species of Acontias are not found; but our elder naturalists have generally confounded them with serpents of a dangerously venomous nature: hence the numerous fabulous stories which are related of them by ancient historians.

ACORN-SHELL. The popular name for the *Balanus* and other Cirrhipeds, which inhabit a tubular shell, whose base is usually formed of calcareous laminae. It is always found attached to some shell or foreign body: it is multivalvular, unequal, and fixed by a stem, or sessile; the valves lie parallel to each other, and in a perpendicular position. The enclosed animal performs its necessary func-

tions by an aperture at the top; for the valves, being destitute of hinges, never open or separate. The tentacula from this animal being feathered, our credulous ancestors conceived the idea that it gave origin to a bird called the barnacle goose; nay, so prevalent was the opinion, that we find inserted in the Philosophical Transactions of this country a grave account of its transformation. [See BARNACLE.]

These curious but common shells are found in all seas, particularly on the coasts of Africa. They are affixed to marine bodies, generally in numerous groups, and the peduncle is sometimes found a foot long. A large log of timber (as Mr. Broderip remarks) covered with these animals, twisting and diverging in all directions, and so thick as entirely to hide the surface of the log, is a strange sight. They look like an enormous collection of serpents to the ignorant; and a living mass of this description, casually thrown into shallow water and left by the tide, has been so termed. Their growth must be exceeding rapid. A ship going out with a perfectly clean bottom will often return, after a short voyage, covered with them.

ACOUCI. (*Dasypsecta acuchi*.) A Rodent quadruped, considerably smaller than the Agouti; it is of a deep olive colour, and

ACOUCI.—(*DASYPROCTA ACOUCHI*.)

has only the rudiments of a tail. It inhabits the woods of Guiana; is of a mild, gentle, and timid disposition; and subsists on nuts, almonds, and other vegetable food.

ACRITA. A term proposed by Professor Owen to be applied to the fourth division of the Animal Kingdom. It is nearly equivalent to the Radiata of Cuvier, in the majority of which there is no distinct nervous system, or separate alimentary canal. In most of the animals composing this sub-kingdom, no muscular fibres are to be perceived, yet of these many contract and expand their bodies, and are furnished with moveable and sensitive tentacles, by which they seize their prey. Many also are capable of locomotion; others, like the plant, are fixed to one spot for life; and some are united together, and form compound animals. There is ordinarily no distinction of sexes; and reproduction takes place either by the simple division of the body, by granular ova, or gemmules which become detached from the parent body, the form of which they ultimately assume.

ACROCHORDUS. A genus of Serpents discovered in Java. They are considered innoxious, and are distinguished from others

by their skin being covered with innumerable small warts or tubercles, which, however, are only apparent when the skin of the living reptile is inflated or in preserved specimens. The only species accurately known at present is the *Acrochordus Javanicus* of Lacepede, chiefly remarkable on account of its diet; which, contrary to the general habit of the order, seems (according to the testimony of Hornstedt) to consist of fruits and other vegetable substances. This animal averages from eight to ten feet in length, the body growing gradually thicker from the head to the vent, and there suddenly contracting so as to form a very short slender tail.

ACROCINUS. A genus of Coleopterous insects belonging to the Longicorn group. The thorax on each side is furnished with a moveable tubercle ending in a spine; the body is depressed; the antennæ very long

HARLEQUIN BEETLE.
(*ACROCINUS LONGIMANUS*.)

and slender; the fore-legs much longer than the others; the elytra are truncated at the end and furnished with two teeth. The largest and best known species is the HARLEQUIN BEETLE (*A. longimanus*) of South America, the common name of which is derived from the agreeable mixture of grey, black and red, on the elytra, giving it a resemblance to the garb of a harlequin.

ACRYDIUM. The name applied by Fabricius to a genus of Locusts, characterized by a carinate thorax; filiform antennæ, shorter than the thorax; and equal palpi. [See LOCUST.]

ACTEON. A genus of Mollusca allied to Doris, a few species of which are found in this country. [For habits, see NUNIBRANCHIATA.]

ACTINIE. These curious and interesting marine animals are closely allied to the

Sea-nettles, spoken of under the head *ACA-LEPHIA*. They are distinguished by the form of their body, which is cylindrical, soft, fleshy, and susceptible of contraction and dilatation. They are also furnished with numerous tentacula, which are appended round the margin of the aperture that serves both as the mouth and vent; and these being not only radiated but of various lively colours, have given rise to the popular names of *Animal-flowers* and *Sea-Anemones*, by which the Actinians are familiarly known. They are found on the shores of every sea, often covering the sides of rocks as with a tapestry of flowers. As in other tribes, each species has its peculiar haunt, and they differ from each other in shape, size, and colour; those in tropical regions far surpassing in gorgeous brilliancy such as are met with in the seas of colder latitudes. These creatures may be cut perpendicularly or across, and each cutting will give origin to a new animal. In development the young may be seen issuing from the mouth; and

SEA-ANEMONES. (ACTINIAE)

sometimes the base of the old animal is discovered, a portion remaining attached to the rock, where it continues to live, increasing in size, becoming more and more rounded, while, in a short time, a mouth, stomach, and tentacula are formed, presenting, to the surprise of an observer, a complete Actinia. At length, the side portions of this base give out globules which are detached, and fix themselves upon adjacent rocks, where they grow and produce a new colony like the parent animal. Among the best known species are the Beadlet Anemone (*A. mesembryanthemum*), of which there is also a strawberry-like form or variety, and the Plumose Anemone (*Actinobola dianthus*). The deep crimson Mediterranean Anemone (*Actinia Jordaica*) is esteemed a great delicacy by the Italians. All the British species are described and figured in Mr. Gosse's "*Actinologia Britannica*."

ACTINOCAMAX. A name given by Miller to the fossil shells of an extinct genus of Cephalopodous Mollusca, apparently connecting the *Belemnites* with the existing *Sepiæ*. They are principally found in the chalk formations of England and Normandy.

ACTINOTROCHA. [See SUPPLEMENT.]

ACULEATA. The name for a section of Hymenopterous insects, whose antennæ are simple, and composed of a constant number of joints, namely, thirteen in the males, and twelve in the females. The larvae have never any feet, and subsist on food which the females or parents provide them with:

one division of them, the *Proctonæ*, or predaceous tribes, which do not collect pollen, feeding upon other insects that have been stored up for them; and the other division, the *Melissææ*, or honey-collectors, feeding upon honey or pollen paste, similarly reserved for their use.

ADAPIS. The name given to a genus of Pachydermatous quadrupeds, now existing only in a fossil state, some imperfect specimens of which were found in the plaster quarries of Montmartre, and described by Cuvier in his great work, *Sur les Ossements Fossiles*.

ADDA. A small species of Lizard, celebrated throughout the East as being efficacious in the cure of various cutaneous diseases to which the inhabitants of Egypt and Arabia are peculiarly subject. It is about six inches long; the body and tail cylindrical, the latter ending in a very sharp point; the face is covered with black lines, which cross each other; the body is of a light straw colour with black bands; and the scales shine as if they were varnished. It burrows in the sand.

ADDAX. (*Antelope addax*.) A species of Antelope, more heavily formed than the generality of *Antilopidæ*, and having large spiral horns, annulated to within about six inches of the points. It lives solitarily or in pairs on the borders and oases of the Nubian deserts. It has remarkably broad hoofs, provided by nature to enable the animal to move the more easily over the fine loose sand. The general colour of the Addax is a greyish-white; but the head and neck are of a deep reddish-brown with a mark of pure white across the lower part of the forehead.

ADDER. (*Vipera berus*.) The Adder, or Viper, is a venomous reptile of the serpent kind, seldom more than two or three feet long, being considerably shorter than the common snake in proportion to its bulk. It is of a dull yellow colour with black spots, and the abdomen entirely black. [See *VIPER*.]

ADEPHAGA. A name given to a family of carnivorous and very voracious Colcopterous insects.

ADESMACEA. A family of Lamellibranchiate Mollusca, which either bore tubular dwellings in rocks, wood, &c., or live in testaceous tubes, their shells being consequently destitute of the hinge ligament. The genera *Pholas*, *Teredina*, *Teredo*, *Fusulina*, and *Septaria* belong to this family.

ADJUTANT, or GIGANTIC CRANE (*Leptoptilus Argala*), the *Argala* of India. This remarkable bird is a native of the warmer parts of India, and is of great use in removing noxious animals and carrion, which it devours with avidity. It stands five feet high, measuring from the tip of the bill to the claws seven and a half feet, and from the tip of each outstretched wing not less than fourteen feet. The head and neck are nearly bare; the beak is extremely large,

ADJUTANT (*LEPTOPTILUS ALBA*.)

long, and strong; and under it hangs a downy pouch or bag, like a dewlap, which is capable of being inflated; the upper part of the bird is of an ash-grey colour, and the under part white. The voracity of the Adjutant is not more extraordinary than its capacity for swallowing: it makes but one mouthful of a rabbit, a fowl, or even a small leg of mutton; and when domesticated its habits of purloining render it necessary to keep all kinds of provision out of its reach. Dr. Latham observes that these birds in their wild state live in companies, and when seen at a distance, near the mouths of rivers, coming towards an observer, which they often do with their wings extended, "may well be taken for canoes upon the surface of a smooth sea: when on the sand-banks, for men and women picking up shell-fish or other things on the beach."

ADONIS BUTTERFLY. [See *POLYOMMATUS*.]

ÆGA. A genus of Isopodous Crustacea,

FISH-LOUSE.

parasitic on fish—hence frequently called *Fish-lice*. They are found in all parts of the world. In Newfoundland the fishermen call the species fish-doctors, and believe that the soft matter (mixed with eggs) found on the under side of the body of the females, is very useful in healing wounds. The adjoining cut will give some idea of the form of the species of this genus, which have the eyes generally large and approximating in front.

ÆGERIIDÆ. A family of Heterocerous Lepidoptera, comprising a moderate number of interesting insects, whose resemblance to various Hymenoptera and Diptera (owing to

the elongate form of the body, and the nakedness of the wings, which are more or less transparent in many of the species) is somewhat remarkable. The antennae are simple, fusiform, or thickened towards the tips, and generally terminated by a small pencil of hairs; the ocelli are distinct, and the labial palpi elevated; the abdomen is elongated; the wings have but comparatively few nervures; and the posterior legs are furnished with very long spurs.—The larvae of these insects are of a cylindrical form, and with naked bodies destitute of a candal horn: they have six pectoral, eight ventral, and two anal feet. They live in the interior of the branches or roots of trees, where they undergo their transformations to chrysalides, whose abdominal segments are armed with transverse rows of recurved points: these enable the chrysalis to push itself not only through the cocoon which the caterpillar had constructed from the decayed roots or branches, but half out of the hole in the stem previously made, it having had the instinct to turn round in its burrow, so that the head of the pupa should be towards the orifice.

The larvae of some species, such as the *Ægeria culiciformis* and *Æ. formiciformis*, feed upon the apple, and that of *Ægeria tipuliformis* upon the pith of currant trees; in the neighbourhood of which the perfect insects may be seen flying, in the hottest sunshine, with great activity, or basking upon the leaves, alternately expanding and shutting the fan-like glossy appendages of hair which decorate the end of the body.

ÆGITHALUS. A name given to a genus of birds (the *Pendulous Tytnice*) of the order *Passerina*. [See *TYTMOUS*.]

ÆGOTHELES. A genus of *Passerine* birds, distinguished by long tarsi, and toes apparently fitted for hopping from bough to bough; the wings comparatively short. The only known species inhabits Australia. In the day it resorts to the hollow branches of trees (or *spouts* as they are called), and holes of the gum trees. It feeds on the smaller *Coleoptera*; lays four or five white eggs, which are nearly round; and has at least two broods a year.

ÆPYORNIS. [See *APPENDIX*.]

ÆQUOREA. [See *ACALEPHA*.]

AGAMA: AGAMIDÆ. A genus and family of Saurian Reptiles. They have thick bodies covered with a loose skin, which is capable of being distended with air, at the will of the animal; the head is short, broad, and flat; the neck also is short, and the tail seldom longer than the body. Different species of them are to be met with in every climate; and as some are capable of changing the colours of their skin, they are in some parts of South America called chameleons. They generally lurk among rocks, heaps of stones, and mouldering ruins, their dull and sombre colours protecting them from observation: the more slender and active kinds, however, ascend trees with great facility, sport among the branches, and feed upon the insects which are generally to be found there

In abundance. Some of the Agamidæ met with in India, South America, and Australia, are very curious; but so numerous are the species, that we cannot here give more than a description of their general characteristics. [See MOLUCH.]

AGAMI, or GOLD-BREADED TRUMPETER. (*Peophia crepitans.*) This interesting bird is about the size of a pheasant or large fowl; has long legs, and a long neck, but a very short tail, consisting of twelve black feathers, over which the rump-plumes hang droopingly. It inhabits the forests of South America, where it is found in numerous flocks; it runs swiftly, and when pursued, trusts to its legs rather than its wings. When domesticated, this bird is a pattern of fondness and fidelity; and is so jealous of its master's caresses, that it attacks the dogs and other animals who venture near him. It is sometimes used to protect domestic poultry from the attacks of birds of prey.

AGATHISTEGUES. A family of Cephalopodous Mollusca, in which the cells are gathered together in small numbers, and heaped up in a globular shape.

AGENIOSUS. A genus of Malacopterygious Abdominal fishes, belonging to the *Siluridæ*.

AGGREGATA. The name given to certain shell-less Mollusca, which are collected together in a common enveloping organized substance containing numerous compartments, from each of which a distinct occupant sends forth a circle of organs to collect food, which, after assimilation, is carried by a common and continuous system of vessels for the support and enlargement of the common dwelling.

AGLAURA. A genus of Dorsibranchiate Annelides, distinguished by having numerous jaws, but no tentacles, or which are entirely hidden; and cirrhi, which perform the office of branchia.

AGOUTI. (*Dasyprocta.*) A genus of Mammalia belonging to the order Rodentia, and classed with the *Cavidae*, or guinea-pig tribe. It is found in great abundance throughout South America; and as it bears some rude resemblance in its form and manner of living to the hare and rabbit, though it varies from both very essentially, it has sometimes been denominated the rabbit of that continent. It, however, varies still more from that animal in its habitude and disposition, than in its form. It has in a great measure the external covering of a hog; so also has it the hog's voracious appetite: it eats indiscriminately of every thing that comes in its way; and, when satiated, conceals the remainder, like the dog and fox, for a future occasion. The Agouti secretes itself in the holes of trees; its ordinary food consisting of potatoes, yams, and the fruits which fall in autumn. It uses its fore-paws, like the squirrel, to convey the food to its mouth; and as its hind legs are very long, it runs, or rather leaps, with considerable swiftness. The flesh is white and tender, and when fat

AGOUTI. (*DASYPROCTA.*)

and well dressed it is by no means unpalatable food. Agoutis are particularly destructive to the sugar-cane: the planters consequently use every means to catch them; and although they are still numerous in most places which are not settled and cultivated, their number is not now to be compared with what it was even long after the first colonists took possession of the West India islands. There is one kind of Agouti called the Mara, or Patagonian Cavy, considerably larger and more elegant than any of the others. Differently from most burrowing animals, it wanders, commonly two or three together, to miles or leagues from its home. It feeds and roams about by day; is shy and watchful; and generally produces two young ones at a birth. Naturalists give to this kind and species the name of *Dolichotis Patagonicus*.

AGRALE. An order of quadrupeds, destitute of teeth, but furnished with very long cylindric tongues, which supply that defect. Of this order there are only two distinct genera, the *Myrmecophaga* and the *Manis* [which see].

AGRIOPUS. A genus of Acanthopterygious fishes, particularly distinguished from other genera by having only nine rays in the pectoral fin. The *xyriopus torus*, or Seahorse, as it is sometimes called, is about two feet long, and is common on the shores of the Cape of Good Hope.

AI. [See SLOTH.]

AIAIA. (*Platalea.*) A bird of the non-bill genus, frequently seen in Brazil, on the banks of rivers. It is of a pale brown, very bright and glossy flesh-colour on the back and wings, while the other parts are all beautifully white. Its flesh is considered wholesome and palatable.

AILURUS. A genus of carnivorous quadrupeds belonging to the family *Ursidæ*. The only known species, first found by Maj. Gen. Hardwicke, is the Wah or Unda (*Ailurus fulgens*). It is about the size of a large cat; the fur soft and thickly set; above, of the richest cinnamon-red; behind more fulvous, and deep black beneath.

PANDA (*AILURUS FULGENS*.)

The head is whitish; the tail annulated with brown; and the soles of the feet are hairy. This elegant animal frequents the vicinity of rivers and mountain torrents, passes much of its time upon trees, and feeds on birds and the smaller quadrupeds.

ALABES. A genus of Malacopterygious apodal fishes, distinguished by having one gill-opening; pectorals well marked, with a disc between them; gill-lids small, with three rays, and pointed teeth. The species inhabit the Indian Ocean.

ALASMADON. A name which has been given to some Bivalve Mollusca, of which the fresh-water Pearl Mussel (*Mya margaritifera*) is an example.

ALATÆ. A family of Mollusca, belonging to the second section of the order Trachelipoda, containing the genera *Rostellaria*, *Pterocera*, *Strophus*, &c. The shells of this family are distinguished by the spreading of the outer lip.

ALAUDA. A genus of granivorous singing-birds, of which there are many species, found in all parts of the globe. They are characterized by a long and straight hind claw, a strong straight bill, and by being able to raise the feathers on the back part of the head into the form of a crest. The greater part of them are migratory: they always build their nests on the ground, and may be considered as peculiarly birds of the fields and meadows. [See LARK.]

ALBATROSS. (*Diomedea*.) A genus of Palmipede birds: the species are the largest of all aquatic birds, the wings of some when extended measuring fifteen feet, and the weight often exceeding twenty pounds. Its plumage is white, with the exception of a few of the wing feathers and some transverse black bands on the back. It has a strong, hard, long beak, of a pale yellow colour: the feet, which are flesh-coloured, are short and webbed; and the wings are long, strong, and narrow. It preys on the wing, and is very voracious; but though formidable from its size and strength, it is not equally courageous, being frequently compelled to yield its prey to the sea-eagles, and sometimes even to the larger species of gulls. These birds are continually met with in the Southern Ocean, and are also seen in immense flocks about Behring's Straits and Kamtschatka in the early part of summer, attracted thither by the vast shoals of fish, whose migrations they follow. Besides the common Albatross, here described, there are two other species of less gigantic proportions,

namely, the Albatross of China and the black-beaked Albatross.

When sailors accidentally fall overboard in latitudes where the Albatross abounds, they find it a most formidable enemy, even should only a few minutes elapse before they can be rescued by their comrades. Its powers of flight are prodigious.—Dr. Arnott mentions an instance of one of these birds following a rapidly sailing ship for two or three days. One species is called by sailors the "Cape

WANDERING ALBATROSS
(*DIOMEDEA EXULANS*.)

Sheep," from flocks of them being seen off the Cape of Good Hope.—Captain Sir J. C. Ross, in his voyage to the Southern Seas, mentions that, in one of the islands frequented by seal hunters, the eggs of these birds, each of which averages about a pound in weight, are much esteemed—while the young birds, when first taken from their nest, are described by them as being quite delicious. It is possible, he adds, the sealers may have acquired the Esquimaux taste.

ALBIONES. A genus of Abranchions Annelides, distinguished by having the body bristled with tubercles.

ALBURNUS. A fresh-water fish, a species of the Cyprinidæ. [See BLEAK.]

ALCA. [See AVK.]

ALCADEÆ. A family of oceanic birds, including the Auks, Puffins, and Guillemots. The power of their wings as organs of flight is generally very circumscribed; but their whole structure is admirably adapted for an aquatic life. The legs are extremely short, but powerful, and placed so far backwards that, in resting on the rocks, the birds appear to stand in an upright position. The toes are usually only three in number, and fully webbed. The bill is generally compressed, and often grooved at the sides, but it varies in form in the different genera. Their food consists of fishes, crustacea, and other marine productions; but they never resort to fresh water. [See AVK, &c.]

ALCEDO: ALCEDINIDÆ. A genus and family of birds, popularly known as Kingfishers, of which there are numerous

exotic species (all distinguished by the splendid colours of their plumage), but only one kind indigenous to this country. Their principal characteristics are, a long, straight, quadrangular bill, thick and pointed; tongue, short, flat, and fleshy; the nostrils at the side of the base of the bill running obliquely; the tail and legs short. These birds for the most part live on fish, which they transfix with the bill as with a spear: they are solitary in their habits, and build their nests in holes on the banks of rivers. [See KING-FISHER.]

ALCIOPE. A genus of Dorsibranchiate Annelides, distinguished by having two foliated cirrhi, or gills, and a couple of branchial tubercles.

ALCYONEÆ, or ALGYONIAN POLY-PES. Under the heads "CORALS," "POLY-PES," and "SPONGES," will be found such particulars as are deemed necessary to describe those singular marine productions. It is, therefore, sufficient to observe in this place, that the *Alcyonæ* are somewhat similar to the last mentioned. They vary much in form, being either lobed, branched, rounded, or existing in a shapeless mass or crust; while the interior substance is of a spongy or cork-like nature, surrounded by tubular rays inclosed in a sort of tough fleshy membrane. The animals are lodged in round cells, separated from each other by thin partitions. They are to be found in all seas, and at various depths, resorting, in general, to sheltered places, or where the water is deep and still.

ALFA. A genus of minute land shells, found in marshy ground, roots of trees, moss, &c.

ALECTOR. (Craz.) A large Gallinaceous bird of America, somewhat like a turkey. They have large rounded tails, composed of stiff quills; build their nests in trees; live on buds and fruits; and may be easily domesticated. [See CURASSOW.]

ALECTURA. [See TALEGALLA.]

ALEPOCEPHALUS. A fish belonging to the *Esocidæ*, or Pike family, found in the depths of the Mediterranean. Head naked, body with broad scales, mouth small, teeth minute and crowded, eyes very large, and eight gill-rays.

ALLIGATOR. (*Alligator lucius*.) This very formidable and ferocious Reptile is found in tropical climates, and agrees in every essential property with the Crocodile once so terrible along the banks of the Nile. There are apparently several species belonging to the order *Sauria*, family *Crocodylidae*, their general plan of structure being the same as that of the lizards. They have a long flat head, thick neck and body, protected by regular transverse rows of square bony plates, raised in the centre into keel-shaped ridges. The mouth is extremely large, extending considerably behind the eyes, and furnished in each jaw with a single row of pointed teeth, all of different sizes, and standing apart from one another. The

tongue is short and fleshy, and firmly attached to the under jaw throughout, so as to be incapable of protrusion; the eyes are placed in the upper part of the skull, and provided each with three distinct lids; and beneath the throat are two small glands

ALLIGATOR LUCIUS

which contain a musky substance. They have five toes on the fore-feet and four behind; but only the three inner toes on each foot are provided with claws. But the most remarkable, and, at the same time, most important organ they possess, is their long taper tail, which is strongly compressed on the sides, and surmounted with a double series of strong plates, which, converging towards the middle, there unite and form a single row to the extremity. Their feet are webbed; but it is to the tail they owe most of their progressive power in the water; and although it impedes their motions on dry land, even there it often becomes a powerful weapon of defence.

The Alligator is prodigiously strong; and its arms, both offensive and defensive, are irresistible. Its ordinary length is from fifteen to eighteen feet, though sometimes considerably more. The shortness of its legs, the vertebral conformation of the backbone, the muscles of the legs, and, in short, its whole frame, are calculated for amazing force. Its teeth are sharp, numerous, and formidable; its claws long and tenacious; but its principal instrument of destruction is its tail, with a single blow of which it is capable of overturning a canoe. Its proper element is the water; but it is also very terrible by land: it seldom, however, unless when pressed by hunger, or with a view of depositing its eggs, quits the water: it usually lays between fifty and sixty of these (which are about the same size as those of a goose, but oblong rather than oval), in one place, and covers them up with sand, leaving them to be hatched by the heat of the sun: it generally happens, however, that half of them are devoured by vultures, or fall a prey to various descriptions of ravenous fishes. Both the Alligator and the Crocodile are supposed to be very long-lived, and their growth is extremely slow.

The most extraordinary accounts are related of the ferocity and strength of this terrible destroyer. It usually floats along the surface, and seizes fish, fowl, turtle, or whatever other prey may fall within its reach; but, this method failing, it is then compelled to venture near the shore, where it conceals itself among the sedges in ex-

pectation of some land animal coming to drink. As the devoted victim approaches, nothing of its insidious enemy is to be seen; nor is the retreat of the former meditated till it is too late. The voracious reptile instantly springs on its prey with much more agility than might reasonably be expected from such an unwieldy creature; and, having secured it with its teeth and claws, instantly plunges into the water and drags it to the bottom, where it is devoured at its leisure. In its depredations along the banks, however, it sometimes happens that the Alligator seizes on an animal as formidable as itself, and meets with a desperate resistance. With the tiger, in particular, which is in the habit of lurking in the vicinity of great rivers, it has frequent contests; and the instant this animal finds itself assailed, he turns about with prodigious agility, and forces his claws into the eyes of the assailant, who immediately plunges with its fierce antagonist into the river, where the struggle continues till the tiger submits to a watery death.

As we have spoken at some length of the Crocodile, and described the different species, it would be inconsistent with our general plan to extend this article much further. We therefore conclude with an anecdote from Waterton's "Wanderings in South America," clearly showing that man is not exempt from the attacks of this ferocious destroyer:—"One Sunday evening, some years ago, as I was walking with Don Felipe de Ynciarte, governor of Angustura on the bank of the Oroonoke, 'Stop here a minute or two, Don Carlos,' said he to me, 'while I recount a sad accident. One fine evening last year, as the people of Angustura, were sauntering up and down here, in the Alameda, I was within twenty yards of this place, when I saw a large Cayman [the common species of Surinam and Guiana] rush out of the river, seize a man, and carry him down, before any body had it in his power to assist him. The screams of the poor fellow were terrible as the Cayman was running off with him. He plunged into the river with his prey: we instantly lost sight of him, and never saw or heard him more."

ALLIGATOR TORTOISE. A genus of the *EMYDÆ*, or Marsh Tortoises, which are carnivorous in their habits: and some of the species, of which this is one, are formidable from their size and ferocity. It is a native of the lakes, rivers, and morasses of Carolina; and it is remarkable for its activity, darting suddenly upon aquatic birds, fishes, or other animals that come within its reach, and snapping them up: from which habit it is sometimes designated as the "Snapping Turtle." The species is the *Chelydra Serpentina*. [See TORTOISE.]

ALOSA. A genus of Malacoptyergious fishes of the *Clupeidæ* or Herring family, greatly resembling the Pilchard and Sardine. *Alosa vulgaris* is the common SHAD (which see).

ALFACA, or PERUVIAN SHEEP. (*Auchenia*.) In form and structure, this

animal bears a strong resemblance to the camel; but is greatly inferior in size, and differs from it in the absence of the hump, the want of water-cells in the stomach, and in the conformation of the foot, which con-

PERUVIAN SHEEP. (*AUCHENIA*.)

sists of two toes completely divided, each with a rough cushion beneath, and provided at the end with a strong short hoof. There appear to be three closely allied species of these animals. That which we are now describing is said to be entirely confined to Peru, where the natives keep vast flocks of them for the sake of the silky lustre and fineness of their wool. It inhabits the more elevated parts of the mountain ranges, living almost on the borders of perpetual snow. [See LLAMA, GUANACO, and VICUNA.]

ALUCITIDÆ. A family of small Lepidopterous insects, nearly allied to the *TINEIDÆ*, but distinguished from that and all others by the wings being singularly divided into narrow feathered rays; the fore wings having two, three, four, or six, and the posterior wings three or six of such rays, which are beautifully feathered on each edge; they are carried horizontally in repose; the antennæ are long, slender, and setaceous; the spiral maxillæ are long; and the legs are long and slender. The larvæ are clothed with very long hairs; they have sixteen feet, and are very inactive; the pupæ are either naked, and enclosed in a transparent silken cocoon; or conical, hairy, and either suspended perpendicularly by a thread, or affixed at the posterior extremity of the body to a layer of silk or leaves. These insects vary in the time of their flight; the *Alucita* frequenting our gardens, and sitting with its beautiful fan-like wings on our hothouses, whilst the *Pterophori*, being crepuscular, fly over low plants. The rays of the wings are composed of the nerves, without any of the intervening membrane, which seems to be transformed into the fringe. In repose the *Pterophori* fold their wings so as to appear to consist of only one broad ray.

ALUTERES. A genus of fishes, belonging to the order *Plectognathi*: they are characterized by a long body, the granulations scarcely visible, and a single spine in the first dorsal; but the pelvis is completely hidden in the skin. For an example, see *OSTRACION*.

AMADAVADE. A small bird of the Finch tribe (*Fringillidae*), having a beautiful red bill. The upper part of the body is brown, the rump dark red, and the prime feathers of the wings are black; as are also those of the tail, which are longest in the middle, and gradually slope to the sides: it is frequently kept as a pet in cages, and lives on seeds.

AMBLYRHYNCHUS. The name given to a genus of Lizards, very much resembling the Iguanas, common on all the islands throughout the Galapagos Archipelago. They differ, however, from the Iguana, in having,—instead of the long, pointed, nar-

AMBLYRHYNCHUS CRISTATUS.

row muzzle of that species,—a short, obtusely truncated head, and also in the strength and curvature of the claws. Mr. Darwin (in his "Journal of Researches," &c.) thus speaks of the one which is termed *Amblyrhynchus cristatus*:—"It lives exclusively on the rocky sea-beaches, and is never found, at least I never saw one, even ten yards inshore. It is a hideous looking creature, of a dirty black colour, stupid and sluggish in its movements. The usual length of a full-grown one is about a yard; but there are some even four feet long. I have seen a large one which weighed twenty pounds. On the island of Albemarle they seem to grow to a greater size than on any other. These Lizards were occasionally seen some hundred yards from the shore, swimming about; and Captain Collnett, in his voyage, says, 'they go out to sea in shoals to fish.' With respect to the object, I believe he is mistaken; but the fact stated on such good authority cannot be doubted. When in the water the animal swims with perfect ease and quickness, by a serpentine movement of its body and flattened tail,—the legs during this time being perfectly motionless and closely collapsed on its sides. A seaman on board sank one, with a heavy weight attached to it, thinking thus to kill it directly; but when, an hour afterwards, he drew up the line, the Lizard was quite active. Their limbs and strong claws are admirably adapted for crawling over the rugged and fissured masses of lava, which every where form the coast. In such situations, a group of six or seven of these hideous reptiles may oftentimes be seen on the black rocks, a few feet above the surf, basking in the sun with outstretched legs." Its habits are entirely aquatic, as well as its food, which consists of seaweed.

The species termed *Amblyrhynchus subcris-*

tatus is terrestrial, and is confined to the central islands of the Archipelago. These "inhabit both the higher and damp, as well as the lower and sterile parts; but in the latter they are much the most numerous. Like their aquatic brethren, they are ugly animals; and from their low facial angle have a singularly stupid appearance. In size, perhaps, they are a little inferior to the latter, but several of them weighed between ten and fifteen pounds each. The colour of their belly, front legs, and head (excepting the crown, which is nearly white), is a dirty yellowish-orange: the back is a brownish-red, which in the younger specimens is darker. In their movements they are lazy and half torpid. When not frightened, they slowly crawl along with their tails and bellies dragging on the ground. They often stop and doze for a minute with closed eyes and hind legs spread out on the parched soil. They inhabit burrows, which they sometimes excavate between fragments of lava, but more generally on level patches of the soft volcanic substance. They feed by day, and do not wander far from their burrows. When attentively watching any one they curl their tails, and, raising themselves on their front legs, nod their heads vertically with a quick movement, and try to look very fierce; but in reality they are not at all so: if one just stamps the ground, down go their tails, and off they shuffle as quickly as they can." They live on the leaves of trees and other vegetable productions; and their flesh is considered a delicate kind of food.

AMBILOTIS. (See WOMBAT.)

AMIA. A small Malacopterygious freshwater fish, found in the rivers of South America. It belongs to the *Clupeidae* family; feeds on Crustacea, and is rarely eaten.

AMMOCETES. A genus of Chondropterygious fishes, allied to the Lampreys, the maxillary ring being without teeth, the fleshy lips semicircular. The common species, *Ammocetes branchialis*, is about the thickness of a goose quill, and is very common in some of the English rivers, where it is known as the Stone Grig. It lodges in the mud, where it preys on worms, insects, &c.; and is of no use but as bait for other fish. It has been accused of sucking the gills of fishes.

AMMODYTE, or LAUNCE. This fish, which is of the Malacopterygious or soft-finned kind, is named Launce from its lance-like shape, and is from eight to ten inches long; its form is slightly square, being rather rounded on the sides, and somewhat flattened above and beneath; the head is small and taper, and the under jaw much longer than the upper; the mouth is destitute of teeth, but at the entrance of the throat are two oblong bones for retaining the prey. The pectoral fins are small, and the tail is slightly forked; the general colour of the body is a greenish-blue on the back, and the belly is either of a silvery white, or of a yellowish hue. These fishes are in England called Sand-eels, being remarkable for their

habit of hurrowing in the sand, in which they find the worms and insects that constitute their chief food. They are in their turn preyed upon by the larger fishes; par-

AMMODYTE, OR LAUNCE.

ticularly by the mackerel and salmon; to the support of the latter, whilst they are in the estuaries of rivers, the Launces are believed to contribute largely. The Launce spawns in the month of May, depositing its eggs in the mud, near the edges of the coast.

AMMODYTES. A genus of Serpents, nearly the size of the Viper, and allied to it in general appearance, though distinguished from it by an erect pointed process on the tip of the snout: its usual colour is either bluish-grey or brown, with a continued black dorsal band resembling that of the viper. A species of this genus is found in many parts of the East, and is so extremely poisonous as to prove fatal in three or four hours.

AMMONITES, or SNAKE-STONES. Spiral fossil shells, of which there are a great abundance in Europe, Asia, and America, especially in the lias, chalk, and oolite formations. They appear like a snake rolled up: some are very small, but occasionally they are met with upwards of three feet in diameter. In some places they are so numerous, that the rocks seem, as it were, composed of them alone. Upwards of 800,

AMMONITES, OR SNAKE-STONES.

species have been already described; and it appears that many of these were very widely

distributed; some being found in the Himalaya mountains, at an elevation of 16,000 feet, and others in various parts of Europe. Their numbers must have been very great, as M. Dufrenoy informed Lamarck that the road from Auxerre to Avallon, in Burgundy, was absolutely paved with them; and we know that it is no uncommon occurrence to find them used in parts of the west of England to pave the roads. It has been suggested that "these animals must have been very important agents, their carnivorous habits duly considered, in keeping the balance among the other tenants of the seas, by preventing the excessive multiplication of crustacea, as well as of other molluscs, and of fishes. The nearest recent ally is *SPIRULA* [which see].

AMCEBA. [See PROTOZOA, p. 548.]

AMPELIDÆ. [See CHATTERERS.]

AMPHIBIA. This term applies only to animals having the power of living, indifferently, at the same time, either upon land or in water, yet we commonly call Seals, Otters, Beavers, &c., besides many Reptiles, amphibious, because their organization disposes them to resort either to the land or water for procuring food, or whose habits are at once terrestrial and aquatic. But this is by far too comprehensive a sense. Linnæus applied the term generally to the third class of his system of zoology, which comprised not only all the animals since more properly denominated Reptiles, such as the Tortoises, Lizards, Serpents, and Frogs, but likewise the Cartilaginous Fishes. It is now admitted, however, that Linnæus was not correct in this classification, and that a truly amphibious animal should possess lungs and gills at one and the same time, for extracting the principle which supports animal life indifferently from either element.

AMPHICELIA. [See SUPPLEMENT.]

AMPHICYON. [See SUPPLEMENT.]

AMPHIDESMA. A genus of small round or rather oblong Shells, slightly gaping and inequilateral, found in the sand on the sea-coasts of tropical countries, and also those of England, France, &c. The *Amphidesma variegatum*, described by Lamarck, is a native of the coast of Brazil. "In most bivalve shells," Sowerby observes, "the cartilage and ligament are united in one mass, or placed close to each other; the contrary in this case gives rise to the name, which signifies double ligament."

AMPHIOXUS, or LANCELET. A small fish of the Lamprey family. Its form is compressed; the head pointed, without any trace of eyes; a delicate membranous dorsal fin extends the whole length of the back; and the tail is pointed. At one time this was regarded as a mollusc, the best known species being the *Limnæa lanceolatus* of Pallas. It is found on the coasts of England and Ireland, in the Forth of Clyde, and in the Mediterranean. Mr. Gray has described a second species from the Eastern seas (*A. Belcheri*).

AMPHIPODA. An order of minute Crustaceans, which have the power of swimming and leaping with great facility, but always on one side. Some are found in streams and rivulets, but most in salt water; and their colour is of a uniform pale red or greenish. In this order the eyes are sessile and immovable; the mandibles are furnished with a palp; the abdominal appendages are always apparent and elongated;

SANDHOPPER.
(*TALITRUS LOCASTA*.)

and they have cilia, which appear to fulfil the office of branchiae. The antennae, ordinarily four in number, are composed of peduncle and slender filament; and the body is mostly compressed and bent. The appendages of the tail generally resemble little pointed stylets. Among the Amphipods most common on our shores are the Sandhoppers, (*Talitrus locusta* and *Orchestia littorea*), found under stones, or under the mass of exuvium thrown up by the tide on sandy shores, in troops of thousands, all active and leaping when disturbed in their retreats. The following passage from Paley's Natural Theology alludes to these minute crustacea: "Walking by the sea-side, in a calm evening, upon a sandy shore, and with an ebbing tide, I have frequently remarked the appearance of a dark cloud, or rather very thick mist, hanging over the edge of the water, to the height perhaps of half a yard, stretching along the coast as far as the eye could reach, and always retiring with the water. When this cloud came to be examined, it proved to be nothing else than so much space filled with young shrimps in the act of bounding into the air from the shallow margin of the water or the wet sand."

AMPHISBÆNA. A genus of Serpents, natives of South America, distinguished by their bodies having nearly the same uniform thickness throughout, by their small mouths and eyes, short tails, and their numerous rings of small square scales. The two best known species are *Amphisbæna olba* and *Amphisbæna fuliginosa*. They are destitute of fangs, and are consequently harmless and inoffensive; living, for the most part, upon ants and other small insects. The colour of

AMPHISBÆNA FULIGINOSA.

the first mentioned species is white, as its name imports; but in some specimens it is tinged with pale rose colour, while in others the head and back incline to a pale yellow or brownish cast. The *A. fuliginosa* is either black with white variegations, or purple with yellow. The eyes of the Am-

phisbæna are covered, and almost concealed, by a membrane; which, added to their naturally diminutive size, has given rise to the popular opinion that the animal was destitute of the organs of sight. The head is so small, and the tail so thick and short, that at first sight it is difficult to distinguish one from the other; and this circumstance, united to the animal's habit of proceeding either backwards or forwards as the occasion may require, gave rise to the credulous belief throughout the native regions of the Amphisbæna, that it has two heads, one at each extremity, and that it is impossible to destroy one by simple cutting, as the two heads mutually seek one another, and soon reunite!

AMPHITHERIUM. [See SUPPL.]

AMPHITRITE. A genus of *Annelides* belonging to the division *Tubicolæ*, and easily distinguished by their large golden-coloured setae, disposed in a comb-like series or in a crown, or in one or several ranges on the front of the head; which may assist them in locomotion, and probably serve them for defence. Around the mouth are very numerous tentacles, and on either side of the commencement of the back are pectinated gills. Some of them compose slight tubes, of a regular conical form, which they carry about with them, when running in search of food; these tubes, which consist of fine grains of sand cemented together with great regularity, are simple cones open at both ends, and not attached; they are usually about two inches long, and may be frequently picked up on our shores. [See *TUBICOLÆ*.]

AMPHIUMA. A genus of Batrachian reptiles which abound in the lakes and stagnant waters of N. America. They first appear in the tadpole form, respiring by means of gills; and inhabiting the water; they afterwards gradually acquire small legs and feet, and would have an appearance similar to the water-newt, were it not for the extreme length of their body. There are only two known species, one characterised by being three-toed, which is three feet long; the other, a much smaller species, having only two toes.

AMPULLACERA. A genus of Mollusca, allied to the *Ampullaria*, two species of which are found in great abundance in New Zealand, living in pools of brackish water, and buried in sandy mud. When touched, the animal enters very deeply into its shell, and is at all times much hidden by it. The head is large, flat, divided into two lobes, and having two sessile eyes; no appearance of tentacula; foot short and square. The shell is thick and globular; mouth round, or oblique, having the lips united; spire short; operculum thin and horny.

AMPULLARIA. A genus of Mollusca found in the rivers of Africa, India, and South America. The shell is generally large, thin and globular; spire very short; whorls rapidly enlarging; the operculum thin and horny, and rarely calcareous. The animal has a large head furnished with four tenta-

cula, with eyes at the base of the two longest, and the foot oval and large. Some of the African species have reversed shells, and all that are natives of Africa and America have the operculum horny; while those which come from India usually have it shelly, and are furnished with an internal groove for its reception parallel to the mouth. The animal has a large bag opening beneath, placed on the side of the respiratory organs; this they fill with water, by which means they can exist for a considerable period out of their natural element; and specimens have been brought from Egypt to Paris alive (before steam navigation was common), although packed up in sawdust. The Indian species lay globular eggs, of a pale green colour, about the size of small peas, which are found in clusters attached to sticks or other things in the water; when dry, they have a beautiful appearance.

ANABAS. A genus of Acanthopterygious fishes, whose respiratory organs are so constructed as to enable them to sustain life for a space of time out of water, by having small apertures or some receptacle, where they can preserve sufficient water to moisten their gills. In cold or temperate regions this is not required, but in tropical countries it often happens that many of the rivers and ponds are dried up. At such times no fish but such as, like the *Anabas*, are furnished with the necessary pharyngeal apparatus for keeping the gills moist, could exist; many of these, however, are able to migrate in search of their natural element, and, it is

CLIMBING PERCH — (*ANABAS SCANDENS*.)

said, they are guided by a remarkable instinct to travel towards the nearest water. One species is called the Climbing Perch. (*Anabas scandens*.) This species, Mr. Daldorf, a distinguished Danish naturalist, says he observed in the act of ascending palm trees, which it did by means of its fins and tail and the spines of its gill-covers; but other naturalists, who have mentioned its habit of creeping on the ground and living out of water, have not confirmed this Dane's account of its climbing propensities. It is a native of India.

ANARATES. A genus of Passerine birds, distinguished by having the superior ridge of the beak rather convex, like that of a Thrush, without emargination. The tail is long and wedge-shaped, which indicates that it is employed for supporting the bird when in a perpendicular position against the trunks of trees.

ANABLEPS. A viviparous fish belonging to the *Maacopterygii*, remarkable for being apparently possessed of four eyes: this is not, however, really the case; for although

the cornea and iris are divided by transverse bands, so that two pupils are observed on each side, yet the other parts of the eye are single. The body is cylindrical, with strong

ANABLEPS TETRAOPHTHALMUS.

scales; the head is flat; the snout blunt, and the mouth across its extremity, with small crowded teeth in both jaws; the intermaxillaries have no peduncle, but are suspended to the nasal bones; the pectorals are in part scaly; the dorsal is small, and nearer the tail than the anal; the pharyngeals are large, and covered with small globular teeth. The species here delineated, *Anableps tetraophthalmus*, inhabits the rivers of Guyana.

ANACONDA. (*Boa*.) A Ceylonese serpent, belonging to the *Boa* family, of enormous magnitude and strength; said to be capable of conquering the largest and fiercest quadruped, and concerning whose actions the most wonderful stories are related. An encounter between one of these serpents and a most powerful tiger is described by an eyewitness in language of fearful interest: "Though unable to get rid of its cruel enemy, the tiger gave it prodigious trouble. A hundred times would it rear up, and run a little way; but soon fell down again, partly oppressed by the weight, and partly by the folds and wreathed twists of the serpent round its body. But though the tiger fell, it was far from being entirely conquered. After some hours it seemed much spent, and lay as if dead; when the serpent, which had many times violently girded itself round the tiger, vainly attempting to break its bones, now quitted its hold, twisting its tail only round the neck of its prey, which was in no condition either to resist or escape. Having by degrees dragged the tiger to a tree, the monster wound its body round the animal and the tree together several times, girding both with such violence that the ribs and other bores began to give way; and, by repeated efforts of this kind, it broke all the ribs, one by one, each of which gave a loud crack in breaking. It next attempted the legs, and broke them severally in the same manner, each in four or five different places. This employed many hours, during all which time the poor tiger remained alive; and at every crack of the bores gave a faint but most piteous howl." A loathsome description of the serpent's "licking the body and covering it with its saliva," preparatory to the act of swallowing, is then given; and the account thus concludes: "Much time was employed in this business; but at length the serpent having prepared the whole to its mind, drew itself up before its prey; and, seizing the head, began to suck that, and afterwards the body, down into its throat." But this, it appears, was the work of some hours; and it had so gorged, that, the next morning, on being attacked by the

party who were witnesses to his monster meal, the serpent could neither defend itself nor retreat; and it was dispatched, by repeated heavy blows on the head with large clobs. It was thirty-three feet in length.

ANAMPSES. A genus of Acanthopterygious fishes found in the Indian seas. They are small and beautifully coloured. The head is without scales; and they are distinguished by having two flat teeth, which project from the mouth, and curve upwards.

ANARRICHAS. A genus of Acanthopterygious fishes, bearing great resemblance to the Blennies, except in their being destitute of ventral fins. Their dorsal fin is composed entirely of simple but not stiff rays, and extends, as does also the anal, very close to the base of the caudal, which last, as well as the pectorals, is rounded. The whole body is soft and slimy. Their front teeth are large and conical, and they may be regarded as fierce and dangerous fishes. [See WOLF-FISH.]

ANAS. The name of a large Linnæan genus of birds, of the order *Anseres*; whose distinguishing character is, that the beak is convex, terminating in an obtuse point; as the Swan, the Goose, the Duck, Widgeon, &c.

ANASTOMA. A genus of land shells, resembling the other *Helices* in every respect, except in the peculiarity of the last whorl taking a sudden turn and reflecting the aperture upwards, so as to present it on the same plane with the spire; so that the animal must walk with the spire of its shell downwards, resting on its foot.

ANATIFERÆ. A name given to a genus of multivalve Cirrhipeds. [See ACORN-SHELL.]

ANATIDÆ. The Duck tribe; a family of web-footed birds; order *Natatores*. They are distinguished by a broad depressed bill, which is covered with a soft skin; and by the hind toe not being included in the web. The bill is furnished with a set of horny laminae at the edge of each mandible, which serve to filter the fluid taken up by the bill, and retain the solid substances taken up with it: the tongue is large and fleshy, the gizzard strong and muscular, and lined with a tough coat, so as to be capable of grinding down the shells of the mollusca on which they feed. Many are migratory, and fly with great strength at a considerable elevation.

ANCHIOVY. (*Engraulis encrasicolus*.) A well known small fish, abounding in many parts of the Mediterranean, particularly on the coasts of Italy, Greece, and Spain: it occurs also, though not to such considerable numbers, on some of our western coasts, as well as on those of France and Holland. It is about four inches long, of a bluish-brown colour on the back, and silvery white on the belly. It is covered with large, thin, and easily deciduous scales, and may be readily distinguished from the Sprat and other kindred species by the anal fin being remarkably short. Mr. Couch, in his Cornish Fauna, says,

"this fish abounds towards the end of summer, and if attention were paid to the fishery, enough might be caught to supply the consumption of the British islands;" and he adds, that he has seen it in the Cornish seas of the length of seven inches and a half!

ANCILLA, or ANCILLARIA. A genus of Mollusca, inhabiting a spiral, univalve marine shell, which, when the animal is alive, is so much covered by the foot, that only the middle of the back can be seen. The species are numerous, and they are chiefly confined to tropical climates. The shells are smooth, and appear as if highly polished.

ANCYLUS. A fresh-water Gasteropodous Mollusc, with a shell similar to that of a Patella. They live in stagnant waters and in rivulets, adhering to stones and aquatic plants.

ANDRENIDÆ. A family of solitary Bees, each species consisting only of males and females. The mandibles are simple, or terminated by one or two notches; in which the labium and terminal maxillary lobes do not form an elongated proboscis,—a character which distinguishes them from the *APIDÆ* [which see]. The antennæ are elbowed; and the hind legs are generally completely clothed with hairs, the trochanters and femora in the females being polliniferous. The species of the genus *Andrena* are very numerous; they make their appearance in the early spring and summer months, and have very much the appearance of hive-bees. The females collect pollen from the stamens of flowers, rather by means of the general hairiness of the body than with the posterior tarsi: this they form, by the addition of a little honey, into a paste for the food of their progeny. They burrow in the ground, in sandy situations, especially if exposed to the sun, often to a considerable depth. At the foot of these burrows they deposit an egg, with a sufficient quantity of this prepared food for the supply of the future grub; which they then cover up, and proceed, cell after cell, closing up the hole at the top with earth, to prevent the attacks of parasites, which, notwithstanding, often succeed in entering the hole and depositing their eggs in the cells.

ANDRIAS. [See SUPPLEMENT.]

ANEMONIES, SEA. [See ACTINIA.]

ANGEL-FISH, or MONK-FISH. (*Squilla Angelus*.) This fish, which is more remarkable for its singularity of form than for its beauty, would seem to connect the genus of Rays and Sharks, were it not for the situation of its mouth, which is an exception from each. It is said to have acquired the name of Angel-fish from its extended pectoral fins having the appearance of wings; and it is called Monk-fish, because its rounded head appears as if enveloped in a monk's hood. The head is large, and the mouth very wide; the teeth are broad at the base, but slender and very sharp above, and disposed in five rows round the jaws. By means of muscles uniting them to the jaws, the teeth are capable of being raised

and depressed like those of the other shark tribe. The eyes are small, and behind each is an orifice in the shape of a crescent. The back is of a pale ash-colour, and extremely rough, having a prickly tuberculated line

ANGEL-FISH. — (SQUATINA-ANGELUS.)

down the middle; the belly is white and smooth; the pectoral fins are large, and extend horizontally to a considerable distance; the ventral fins are also placed in the same manner, and the tail is bifurcated.

The Angel-fish is met with on many parts of the British coasts, but is most numerous on the Southern. It is very voracious, and feeds on the smaller flat-fishes, which swim close to the bottom; and, like them, it occasionally hides itself in the loose soft soil. It is exceedingly fierce, and dangerous to approach; nor does it look less fierce or malignant than it really is. It sometimes attains the length of seven or eight feet, and weighs nearly a hundred pounds; but instances of this are comparatively rare. Formerly the flesh was held in high estimation, but it is now disregarded as rank and coarse. The skin, being rough, is used to polish wood and ivory, as well as for other uses in the arts.

ANGLER. (*Lophius piscatorius*.) This extraordinary fish is not unfrequently met with on our coasts, and is known also by the names of the Fishing-frog, Toad-fish, and Sea Devil. It is the most uncouth, ill-shapen of the piscatory tribe, resembling the frog in its tadpole state, from which it derives one of its common appellations. The head, which is circumferentially larger than the whole body, is flat on the top; the mouth nearly as wide as the head; the lower jaw is considerably longer than the upper, and bearded all round the edge; both jaws are armed with numerous sharp conical teeth, curving inwards. The nostrils have no external orifice, but there are two internal ones which supply their place; the eyes are large,

ANGLER. — (LOPHIUS PISCATORIUS.)

the irides brown, and the pupils black; pectoral fins broad, rounded at the edge, and wide at the base; ventral fins broad, thick, and fleshy, jointed like arms, and

divided in the insides. The colour of the upper surface of the body is brown, the lower part white, and the skin smooth throughout: ventral and pectoral fins white; tail nearly approaching to black. The Common Angler is usually about three, but sometimes it is six feet in length; lives, as it were, in ambush, at the bottom of the sea; and by means of its fins it stirs up the mud and sand so as to conceal itself from other fishes on whom it preys.

The most interesting circumstances connected with the habits of this animal refer to the mode in which it secures its living dainties, and the singular apparatus specially provided for this purpose. In the annexed cuts it will be noticed that there are two rod-like filamentary appendages affixed to the snout immediately in front of the closely approximated eyes. These filaments are bony, elastic, and comparatively stout below where they are attached; both are moveable, the anterior one being articulated to the snout in a very remarkable manner. This joint, in fact, precisely resembles two links of an ordinary chain, so that the upper link, answering to the hollowed out lower end of the filament, plays freely within the circle of the

lower link. It will be further observed that the tip of this anterior filament — a veritable Lilliputian fishing-rod — is provided with a pendulous flattened membrane, resembling a small flag; this can be hoisted at the animal's will, and, whilst it calls the attention of little fishes in the neighbourhood, at the same time serves as a bait, or, more strictly, a decoy. When about to take a meal, the body of the Fishing-frog is carefully concealed by mud stirred up in the way already mentioned; and the bait being now elevated above the muddy zone, and shaken to and fro with a duly winnig or "killing" effect, the prey immediately gather round; whilst, no sooner have a sufficiently numerous group assembled — all being merrily engaged in tugging away at the decoy — than they are remorselessly and by one fell swoop consigned by the Sea-Devil into its capacious stomach. Surely this is a cogent illustration of "final intention."

Allied to the Common Angler are six others:—1. The CORNISH ANGLER (*Lophius Cornubicus*). 2. The MURICATED ANGLER (*Lophius muricatus*). 3. The BEAKED ANGLER (*Lophius rostratus*). 4. The HABLEQUIN ANGLER (*Lophius histrio*). 5. The STRIPED ANGLER (*Lophius striatus*). 6. The MARBLED ANGLER (*Lophius marmoratus*).

ANGUILLA. [See EEL.]

ANHINGA, or WHITE-BELLIED DARTER. (*Plotosus anhingae*.) A very elegant species of the *Colymbidae*, or Diver family, common in some parts of Brazil. Its body is about the size of a tame duck's, but its length, from the tip of the beak to that of the tail, is nearly three feet. It has a long, slender bill, yellowish at the base; a small head; the neck long, round, and slender, and covered with soft downy feathers of a rufous grey colour; while those on the breast, belly, and thighs are of a silvery whiteness. The plumage at the beginning of the back is brown, each feather having an oblong spot of whitish yellow in the centre, so that it appears speckled; the rest of the back is black; and the tail consists of shining black feathers tipped with grey. The legs are remarkably short, the thighs feathered, and the claws very sharp and crooked. The Anhinga builds its nest on trees, on which it roosts at night and when not on the water, being very rarely seen on the ground. It feeds upon fish, which it catches most dexterously, darting upon them with great rapidity.

These birds delight to sit in little communities, on the dry limbs of trees, hanging over still waters, with their wings and tails expanded. When any one approaches, they will drop off the limb into the water as if dead, and for a minute or two are not seen; when on a sudden, at a great distance, their long slender heads and necks only appear, so that whilst swimming they greatly resemble snakes, no other part of them being visible, except occasionally the tip of the tail.

ANI. [See CROTHERACA.]

ANIMAL FLOWER. A name given to one species of *Actinia*, the animal bearing some resemblance to a flower with a radiated disc; its tentacula being disposed in regular circles, and tinged with a beautiful variety of bright lively colours, as the marigold, anemone, &c. [See *ACTINIA*.]

ANIMALCULÆ, or ANIMALCULES.

A term applied to minute animals of various orders, many of which can only be seen by the aid of a microscope. [See *INFUSORIA*.]

ANNELIDA. A class of articulate animals, comprising species which may be characterized as possessing an elongated body, divided into numerous segments, marked by transverse lines, and generally furnished with a series of bristly appendages which serve as legs. Many of the *Annelida* are red blooded, and have a complete apparatus for circulation and respiration. Some live in fresh, others in salt water; and others, like the hair-worm, are amphibious. In some the bristly appendages are implanted on fleshy tubercles; in others they are only represented by a few short stiff hairs; while in other instances, as in the Leech, there is no trace of any members or appendages to the body. The bristles are usually sharp, and sometimes barbed, serving not only to attach the animals to soft substances, and to hold

firmly on to rocks and other solid surfaces, but to aid their movements through the water. When there are no locomotive appendages, the extremities of the body are usually furnished with suckers.

ANNULATA SEDENTARIA. A tribe of soft, elongated, and worm-shaped animals, inhabiting a tube which they never quit. The body has either transverse segments or wrinkles; the head, eyes, and antennæ are furnished with retractile knobs, in lateral rows. They are usually attached to marine substance, and the greater part of them are carnivorous.

ANOÆ. (*Anoa depressicornis*.) A ruminating animal of Sumatra, at present; but imperfectly known to naturalists; by some considered a small species of wild buffalo, and by others a kind of antelope. The living animal has not been brought to this country, but several skulls and horns are deposited in the British Museum, and in that of the Zoological Society. The horns are wrinkled, but perfectly erect and straight, and the head is long and narrow.

ANOBIUM. A genus of Coleopterous insects, some of which inhabit the interior of our houses, where they do much injury in their larva state by gnawing furniture, books, &c., which they pierce with little round holes; others feed upon wafers, preserved specimens of natural history, &c. The curious sound made by one of these has given it the name of *DEATH-WATCH* [which see].

ANODONTA. A fresh-water Molluscous animal, inhabiting a thin, inequivalve, inequilateral shell; hinge straight, with either no teeth or mere rudiments; shell transverse; ligament external. The valves are thin, large, and pearly; and from their shape and lightness they are used in France for skimming milk. The *Anodonta* is found in every quarter of the world.

ANOLIS. A genus of reptiles peculiar to America, and supplying the place that is occupied by the chameleons in the Old World. Cuvier distinguishes them from the *Iguanas*, by their having teeth in the palate of the mouth as well as in the maxillary bones. The *Anolis* is a small, slender, active animal; frequenting woods and rocky places; and running, leaping, and climbing with singular agility. It is furnished with a loose skin or lag beneath its throat, which, when inflated, frequently changes its colour: in short, whenever these creatures are under the ex-

ANOLIS

citement of fear, anger, or love, the skin assumes an endless succession of varying hues. They are of more slender proportions than the chameleon, and more agile in their movements; they feed chiefly upon flies and other insects, and inhabit the neighbourhood of marshes and other moist places where insects mostly abound. The head is long, straight, and flattened; the body and tail are long and slender, both being covered with small round scales, which give the skin the appearance of fine shagreen. The hind legs are rather longer than those before; and each foot has five toes. Several species of this genus inhabit the West India Islands; the largest of them not being more than a foot long.

ANOMIA. A genus of marine Mollusca remarkable for the perforation of one of its valves by a large aperture; through which a strong tendinous ligature passes, to be inserted into a third plate, by which the animal adheres to foreign bodies. They are usually found attached to oyster and other shells. This family has long been known in a fossil state, and contains many species. They may be divided into two genera; the inarticulate, and the multarticulate: in the inarticulate *Anomia*, the hinge of the under valve forms a large cavity, the corners of which make two prominences or joints, and the upper valve is indented into it by corresponding depressions: in the multarticulate *Anomia* the hinge lies in a long straight line, and is set with many teeth.

ANOMURA. A section of Decapod Crustaceans, consisting of many genera; the habits of some of which, as the Hermit or Soldier Crab (the type of the genus *Pagurus*), are highly curious and interesting. [See HERMIT CRAB.]

ANOPLOTHERIUM. A genus of extinct quadrupeds, found in a fossil state, and which seem to range between the Pachydermata and the Ruminantia. They had six incisor, four canine, and four molar teeth, in each jaw, forming a continued line; and the feet had only two toes, sheathed by separate hoofs; but the toes had separate metacarpal and metatarsal bones, as in the hog, instead of springing from a single cannon bone, as they invariably are among the Ru-

SKELTON OF ANOPLOTHERIUM.

minantia. The skull partook of the form of that of the Horse and the Camel, not having a prolonged snout. It is observable, that among the remains which have been discovered there are several species, varying

considerably in their general formation; some presenting a light, slender, and graceful form, probably a fleet and active inhabitant of the dry land, having much of the contour of the gazelle; while another was heavy, bulky, and short-limbed, with a flattened tail, as if aquatic in its habits. But it seems fully demonstrated that these animals were all herbivorous, differing but little in this respect from the Tapirs and Rhinoceroses at present existing.

ANOPLURA. An order of parasitic insects—the *Louse* and its allies; whose presence on the human body is usually regarded as an indication of habitual filthiness. It is to be observed, however, that the inferior animals are subject to them, and that almost every quadruped and bird is infested with some one or other of these parasitic insects.

ANSERES. The third order of the Linnean class *Aves*, thus characterized: A smooth beak, covered with skin, gibbous at the base, and broader at the point; feet formed for swimming, having palmated toes connected by a membrane; the legs thick and short; and the body bulky, plump, and downy: food fishes, frogs, aquatic plants, worms, &c. The Goose furnishes a ready example.

ANT. (*Formica*.) A well-known genus of Hymenopterous insects, famed from all antiquity for their social and industrious habits, for their love of order and subordination, and for being a pattern of unremitting industry and economy. They are distinguished from other *Hymenoptera* by their habit of residing under ground in numerous societies, and by the existence of *neuters* among them, by which class the labours of the community are chiefly performed. The males have always four wings; the females are larger than the males, and only possess wings during the pairing season; but the *neuters* have none at any period.

ANT (*FORMICA RUFA*). MALE AND FEMALE

The common European Ants are, in general, either *black* or *red*, and they are of different sizes. Some are furnished with stings, and others are wholly destitute of them: such as have stings use them for their defence; and such as are unprovided with these weapons have a power of squirting an acid pungent fluid, which inflames and irritates the skin like nettles. The eyes are extremely black; and under them are two small horns or feelers, composed of twelve joints, all covered with fine silky hair. The mouth is composed of two crooked jaws, which project, and in each of which appear incisors resembling teeth. The breast is covered with fine silky hair, from which project six legs,

having the extremities of each armed with two small claws, which assist the insect in climbing. The body is of a brown chestnut colour, shining like glass, and covered with extremely fine hair. From this formation, it would appear, the Ant seems bolder and more active than any other creature of the insect tribe of the same size; and, indeed, it possesses sufficient intrepidity to attack an animal many times larger than itself.

The nests of Ants are differently constructed in the different species, but all are very curiously and regularly arranged. "If an Ant-hill," says Mr. Broderip, "be examined any time after Midsummer up to the close of Autumn, there may be seen mixed with the wingless workers a number of both males and females furnished with white glistening wings. These, however, are neither kings nor queens in the state, at least so far as freedom of action is concerned, for they are not allowed to move without a guard of workers to prevent their leaving the boundaries; and if one straggles away unawares, it is for the most part dragged back by the vigilant sentinels, three or four of whom may, in such cases, be seen hauling along a single deserter by the wings and limbs. The workers, so far from ever facilitating the exit, much less the departure of the winged ones, more particularly the females, guard them most assiduously in order to prevent it, and are only forced to acquiesce in it when the winged ones become too numerous to be either guarded or fed. There seems, indeed, to be a uniform disposition in the winged ones to desert their native colony; and as they never return after pairing, it would soon become depopulated in the absence of females. The actual pairing does not seem to take place within the ant-hill, and we have observed scouts posted all around ready to discover and carry back to the colony as many fertile females as they could meet with. It is probable that, soon after pairing, the males die, as do the males of bees and other insects; for, as the workers never bring any of them back, nor take any notice of them after leaving the ant-hill, they must perish, being entirely defenceless, and destitute both of a sting and of mandibles to provide for their subsistence. The subsequent proceedings of females are very different, and of curious interest. It was supposed by the ancients that all Ants, at a certain age, acquired wings; but it was reserved for the younger Huber, in particular, by means of his artificial fornicaries, to trace the development of the wings in the female from the first commencement, till he saw them stripped off and laid aside like cast clothes."

"Having directed my close attention to the eggs of ants," says Huber, "I remarked that they were of different sizes, shades, and forms. The smallest were white, opaque, and cylindrical; the largest transparent, and slightly arched at both ends; while those of a middle size were semi-transparent. On holding them up to the light, I observed a sort of white oblong cloud; in some, a transparent point might be remarked at the superior extremity; in others, a clear zone above and underneath the little cloud. There

were some whose whole body was so remarkably clear as to allow of my very distinctly observing the rings. On fixing attention more closely upon the latter, I observed the egg open, and the grub appear in its place. Having compared these eggs with those just laid, I constantly found the latter of a milky whiteness, completely opaque, and smaller by one half, so that I had no reason to doubt of the eggs of ants receiving a very considerable increase in size; that in elongating they become transparent, but do not at this time disclose the form of the grub, which is always arched." When the eggs are at length hatched, the young grubs are fed either by the neuters (called also nurse-ants and workers) when any of these are in the colony, and by the mother when she is alone, by a liquid disgorged from the stomach, as is done in a similar way by wasps, bumble-bees, and certain birds.

"When the larvæ have attained their full growth they spin a silken covering, called by entomologists a cocoon: in this they completely enclose themselves, and remain perfectly quiescent without receiving any nutriment, awaiting the final change when they are to assume the form of Ants. This stage of its existence is the pupa, but is commonly though very erroneously called the egg. Ants' eggs, as they are vulgarly called, are a favourite food for partridges and pheasants, and are eagerly sought after by persons who rear these birds from the egg. The cocoon containing the pupa is of a long cylindrical form, of a dirty white colour, and perfectly without motion. The pupa within the cocoon has now attained the form which it will finally possess; its limbs are distinct, but want strength and consistence, and are covered by a skin which has yet to be cast. In colour it changes from white to a pale yellow, then to red, and finally becomes almost black; its wings, if a male or female, are distinctly visible, but do not assume the shape, size, or character, they are hereafter destined to bear." — *Neuman's Hist. of Insects.*

In England, ant-hills appear formed and arranged with very little regard to order or regularity; but in the more southern parts of Europe they are constructed with amazing ingenuity. They are generally formed in the vicinity of some large tree on the bank of a river; the former for the purpose of securing food, and the latter for supplying them with that abundant moisture which is requisite for the use of these insects. The ant-hill is of a conical shape, and is composed of leaves, bits of wood, sand, earth, stubble, gun, and grains of corn; all united into a compact body, perforated with galleries down to the bottom, and having a variety of tunnels or passages throughout the interior, the number of these avenues depending entirely on the population and extent of the nest. At its commencement the nest is simply an excavation made in the earth; a number of the labourers wander about in quest of materials suitable for the superstructure; others carry out particles of earth from the interior, and these particles, interspersed with the fragments of wood and leaves brought in continually from every

quarter, give a kind of stability to the edifice: it daily increases in size, the Ants taking care to leave the spaces required for the galleries which lead to the exterior; while the dome contains a number of spacious chambers or recesses, which communicate with each other by means of galleries constructed in a similar manner. Thus we see that although the exterior of the hillock always presents the appearance of a dome, and appears but a careless heap, it is in reality a most ingenious device for keeping out water, for evading the effects of the wind, and the attacks of enemies; and yet more especially for receiving and husbanding the heat of the sun. There are external apertures, to permit free egress to the multitude of labourers of which the commonwealth is composed; and from the commencement of the warm season they are constantly employed, till the unpropitious winter again suspends their exertions, and terminates their annual industry.

The working Ants are not only employed in sustaining the idlers at home, but in providing sufficient food for themselves. They subsist on various provisions, both animal and vegetable; killing and devouring all weaker insects, as well as in seeking ripe fruits and whatever appears to contain saccharine matter. When they are unable to eat the whole of the substance they have found, they devour what they can; and, tearing the rest in pieces, load themselves with the spoil. When they meet with an insect which they are singly incapable of mastering, several of them join in the attack; its destruction generally follows, each Ant assisting in carrying away a portion of the booty. When a single Ant chances to make a fortunate discovery, it immediately communicates the information to others, and the whole republic soon appear in motion. But while they are thus busied in feeding abroad, and carrying in provisions for the use of those which continue inactive at home, they are by no means unmindful of posterity. The female Ants soon begin to lay their eggs, which are immediately carried to the safest situation, at the bottom of the hill, where they are assiduously defended by the labourers, who always display the fondest attachment to the rising progeny, either attending to the safety of the larvae, or in feeding the newly born insects. Who, indeed, has not seen them, when the gardener or some formidable enemy has demolished their whole habitation, affectionately solicitous of their offspring, and running wildly about, each loaded with a young one, not unfrequently as large as itself.

For some time the new born Ants remain under the careful superintendence of the labourers: they are attended in all their wanderings about the nest, and are made acquainted with all its galleries and chambers: the wings of the males and females, previously folded together, are extended, and this is always accomplished with such skill and tenderness, that these delicate members are never injured by the operation: in fine, these founders of future colonies are in all respects served with unremitting at-

tention until their final departure from the nest.

In the autumn, says Mr. Newman, we frequently observe one of their hillocks closely covered with a living mass of winged Ants, which continue to promenade, as it were, over its entire surface: they mount on every plant in the vicinity of their nest, and the labourers (for now the entire population of the nest has turned out) accompany them as closely as possible, following them to the extreme tip of every blade of grass; and when at length those possessed of wings spread them in preparation for flight, the labourers will often hold them back, as if loath to trust them alone. . . . When the air is warm and still they rise in thousands, and sailing, or rather floating on the atmosphere, leave for ever the scene of their former existence. Each female, immediately on alighting from her aerial voyage, examines the situation in which chance has placed her, and if she find it adapted to her purpose, she turns her head back over her shoulders, and with her sharp mandibles tears off the wings which bore her from the place of her nativity. Strange as this propensity may seem, it is dictated by an unerring instinct, for the object for which wings were given her is now accomplished, and henceforth they would prove an incumbrance, and retard rather than assist, the performance of her duties. Sometimes a few workers, wandering at this period of excitement far from their home, may happen to meet with her, and if so, they unite their labours with hers in excavating a small and humble dwelling in the earth, which serves as the nucleus of a future colony: in all operations the female, now a queen, takes a most energetic part, and continues to labour until she has laid eggs, when the conduct of the workers undergoes a great change, for they now treat her with the most marked respect, and consider her worthy the honours of a sovereign.

The ingenious author we before quoted gives a very curious account of what he terms the *Slave Ants*, which in substance is as follows: The most remarkable fact connected with the history of Ants, is the propensity possessed by certain species to kidnap the workers of other species, and compel them to labour for the benefit of the community, thus using them completely as slaves; and, as far as we yet know, the kidnappers are red or pale-coloured Ants, and the slaves, like the ill-treated natives of Africa, are of a jet black. The time for capturing slaves extends over a period of about ten weeks, and never commences until the male and female Ants are about emerging from the pupa state, and thus the ruthless marauders never interfere with the continuation of the species. This appears to be a special adaptation of their peculiar instinct; for if the attacks were made on the nests of the Negro Ants, before those by whom the race is propagated are ready to issue forth, it must speedily become extinct. When the Red Ants are about to sally forth on a marauding expedition, they send scouts to ascertain the exact position in which a colony of negroes may be found; these

scouts having discovered the object of their search, return to the nest and report their success. Shortly afterwards the army of Red Ants marches forth, headed by a vanguard, consisting of only about eight or ten Ants, which is perpetually being changed,—the individuals which constitute it, when they have advanced a little before the main body, halting, falling into the rear, and being replaced by others. When they have arrived near the Negro colony, they disperse, wandering through the herbage, and hunting about, as if aware that the object of their search was near, though ignorant of its exact position. At last they discover the settlement, and the foremost of the invaders rushing impetuously to the attack, are met, grappled with, and frequently killed by the negroes on guard: the alarm is quickly communicated to the interior of the nest; the negroes sally forth by thousands, and the Red Ants rushing to the rescue, a desperate conflict ensues, which, however, always terminates in the defeat of the negroes, who retire to the innermost recesses of the habitation. Now follows the scene of pillage: the Red Ants with their powerful mandibles tear open the sides of the negro ant-hill, and rush into the heart of the citadel. In a few minutes each of the invaders emerges carrying in its mouth the pupa of a worker negro, which it has obtained in spite of the vigilance and valour of its natural guardians. The Red Ants return in perfect order to their nest, bearing with them their living burdens. On reaching the nest the pupæ appear to be treated precisely as their own, and the workers when they emerge perform the various duties of the community with the greatest energy and apparent good-will. [For an account of the White Ants, which belong to a totally different order of insects, see TERMITES. See also DRIVER ANTS.]

The following short passage from Mr. Darwin's Observations on the Natural History of Rio de Janeiro will give the reader a good idea of the magnitude of the Ants' nests there: "Travelling onwards, we passed through tracts of pasture, much injured by the enormous conical Ants' nests, which were nearly twelve feet high. They gave to the plain exactly the appearance of the mud volcanoes at Jorullo, as figured by Humboldt." And in Gardner's Travels in Brazil we read the following remarks on the immense multitudes of Ants which are found there. "When near Rio de Janeiro," he says, "we passed many habitations belonging to poor people of colour, mostly fishermen. Before reaching the foot of the mountain over which the road leads to Tijuca, we passed a migrating body of small Black Ants. The immense number of individuals composing it may be imagined from the fact, that the column was more than six feet broad, and extended in length to upwards of thirty yards. The ground was completely covered with the little creatures, so closely were they packed together." The species also are more numerous than naturalists are aware of: he says that near Pernambuco he noticed more than 25 different species.

ANT-EATER. (*Myrmecophaga*.) A genus of animals, of the Cuivarian order *Edentata*. Their distinguishing characteristics are, that the body is covered with hair, the mouth is small, and the tongue long and cylindrical, calculated to supply the want of teeth, from being covered with a glutinous saliva, by means of which they entrap and devour the insects upon which they live and from which they derive their name. The head is very long, but the tongue is much longer, and capable of being extended to a surprising distance beyond the snout; the eyes are particularly small, the ears short and round, the legs thick and strong, but most unfavourably formed for locomotion, and consequently their pace is remarkably slow. There are three distinct and well-defined species in South America; and these, with one or two others, we shall briefly describe.

The **GREAT ANT-EATER**, or **ANT-BEAR** (*Myrmecophaga jubata*), is by far the largest of the Ant-eaters, and is covered with long, coarse, shaggy hair, except the head, where it is short and close; it has a very long and slender head, and a bushy black tail of

GREAT ANT-EATER — (*MYRMECOPHAGA JUBATA*.)

enormous size and length, the whole animal often measuring eight feet from the tip of the snout to the extremity of the tail. Being plantigrade, it stands lower on the hind legs than before, which is the case with bears and other quadrupeds similarly formed. It has four toes on the fore-feet, the second and third being provided with long, sharp-pointed, and trenchant claws; so that nothing upon which it has an opportunity of fastening can escape. The hind feet have five toes, furnished with short weak claws, resembling those of ordinary quadrupeds. The prevailing colour of this animal is a deep grey, with a very broad band of black running from the neck downwards on each side of the body; its habits are slothful and solitary; and it sleeps during the greater part of the day. It lives exclusively on ants, to procure which it opens their hills with its powerful crooked claws, and draws its long flexible tongue, which is covered with glutinous saliva, lightly over the swarms of insects who flock from all quarters to defend their dwellings. It is a native of Brazil and Guiana. It seems almost incredible that so robust and powerful an animal can procure sufficient sustenance from Ants

alone; but this circumstance has nothing strange for those who are acquainted with the tropical parts of America, and who have seen the enormous multitudes of these insects, which swarm in all parts of the country to that degree, that their hills often almost touch one another for miles together. The favourite resort of the Great Ant-eaters are the low swampy savannahs, along the banks of rivers and stagnant ponds.

The TAMANDUA (*Myrmecophaga tamandua*), a smaller kind of Ant-eater, is about the size of a full-grown cat; the head not being so disproportionately long as the species above described, though it is of the same general cylindrical form, and equally truncated at the end. The conformation of the extremities, and the number of the toes is in every respect the same as in the Great Ant-eater; but the tail is prehensile, which makes it essentially an arboreal quadruped; while, instead of having long shaggy hair, it is short, shining, and somewhat silky, like the finest wool. There are several varieties of this species, differing chiefly in colour; they reside exclusively on trees, living on termites, honey, and (according to Azara, in his Natural History of the Quadrupeds of Paraguay), bees, which in those countries form their hives among the loftiest branches of the forest, and, having no sting, are readily despoiled of their honied treasure.

The LITTLE ANT-EATER (*Myrmecophaga didactyla*) is an animal of considerable elegance, and not larger than a squirrel: the head is small, the snout sharpened and slightly bent downwards; the fore-feet have only two claws on each, the exterior one much larger and stronger than the interior; the ears are very small, and hid in the fur; the eyes are also small. The whole animal

LITTLE ANT-EATER. — MYRMECOPHAGA DIDACTYLA.

Is covered with a beautiful soft and curled fur of a pale yellow-brown colour; the tail is thick at the base, tapering to the tip; and being prehensile, it greatly assists the Little Ant-eater's operations in its search for insects among the trees, on which it resides.

The STRIPED ANT-EATER. (*Myrmecophaga striata*.) This is a native of Guiana:

it is about twenty inches long from the tip of its snout to the end of its tail; the nose is taper, the upper mandible extending very far beyond the lower; the body and tail are of a tawny colour, with the under parts white; the body marked with broad, distant, blackish, transverse stripes, and the tail annulated with similar ones. [For SPINE ANT-EATER, see ECHIDNA.]

ANTELOPE. (*Antelope*.) A genus of hollow-horned Ruminants, of which there are many species, each differing from the other in some important point, but agreeing in the grand leading characteristics. Thus,

SKULL OF ANTELOPE

speaking generally, it may be said, that Antelopes are of graceful and symmetrical proportions; of a restless and timid disposition, extremely watchful, of great vivacity, remarkably swift and agile, and most of their boundings inconceivably light and elastic. Their horns, whatever shape they assume, are round and annulated; in some species straight, in others curved and spiral; in some the females have no horns, in others they are common to both sexes. They all possess a most delicate sense of smell; their eyes are proverbially bright and beaming; and so fleet are they, that the huntsman is often obliged to call in the aid of the falcon, trained for the purpose, to seize on the animal and arrest its progress, in order to give the greyhounds an opportunity of overtaking it. Their hair is generally short and smooth, and of an equal length over every part of the body: some species, however, have manes on the neck and shoulders; and a few are furnished with long hair on the chin and throat. The ears are long and pointed; the tails short, and tufted at the extremity. For the most part Antelopes are gregarious, some species forming herds of two or three thousand, while others keep in pairs, or in companies of five or six. They often browse like the goat, and feed on the tender shoots of trees; and the flesh of those which are taken in the chase is usually of excellent flavour.

The *Antilopidae* seem to be a connecting link between the Goat and the Deer. Like the goat, they never shed their horns; but, on the other hand, their size and the delicacy of their conformation, the nature and colour of the hair, their fleetness, &c., are striking points of resemblance to the deer tribe. The hind legs, like those of the hare, being

longer than the fore ones, not only give additional swiftness, but greater security, in ascending and descending precipices, a practice in which the Antelope greatly delights. The majority of the species are brown on the back, and white under the belly, with a black stripe separating those colours. The tail is of various lengths, but always covered with pretty long hair; and the ears, which are beautiful and well placed, terminate in a point. The hoof is cloven, like that of the sheep; and the horns are perennial. The length, size, and turn of the horns, the different spots in the skin, or diversities of size, constitute the chief distinctions which mark the several species. They mostly inhabit the torrid regions, or such parts of the temperate zone as are nearly contiguous, frequenting the cliffs and ledges of rocks, or traversing vast untrodden wildernesses. Africa appears to be their great nursery, but many kinds are natives of Asia; very few are met with in Europe; and it is remarkable that, notwithstanding the warmth of South America is well suited to their nature, only a single species of Antelope is to be found in any part of the New World.

Having made these general remarks, it is necessary, for the sake of perspicuity, to consider Antelopes as divided into sub-genera, or families. It has been customary to class them as follows:—1. True Antelopes; 2. Bush Antelopes; 3. Capriform (or goat-like) Antelopes; and 4. Bovine (or ox-like) Antelopes. But some late writers on zoology have rendered the sub-division infinitely more minute; the species in many instances closely bordering on each other, while there are others in which scarcely any corresponding features can be distinctly traced. Thus, as an eminent naturalist has remarked, "the genus Antelope has become a kind of zoological refuge for the destitute, and forms an incongruous assemblage of all the hollow-horned ruminants together. So diversified are its forms, and so incongruous its materials, that it presents not a single character which will either apply to all its species, or suffice to differentiate it from conterminous genera."

THE COMMON ANTELOPE, OR SASIN. (*Antelope Cervicapra*.) This elegant specimen of the Antelope tribe is a native of many parts of Africa, and also of India. It is somewhat smaller than a fallow deer, and is remarkable for the peculiar beauty of its long spiral horns, which are distinctly marked by numerous prominent rings; its colour is a reddish tawny brown above, and white below; the legs are long and delicate, the body round, but light and well formed; the eyes large and expressive, and their orbits white. They are extremely wary, and when feeding or lying down are guarded by sentinels, who give the alarm on the slightest appearance of danger; and such is their fleetness and activity, that they often vault over nets ten feet high, and when pursued, will pass over as many yards at a single bound. (See SPRINGBOK, PRONGHORN, Gnu, GAZELLE, KODU, STEENBOK, NYLOHAR, &c.]

COMMON ANTELOPE. — (ANTELOPE CERVICAPRA.)

ANTHICIDÆ. A tribe of Coleopterous insects, possessing simple or but slightly serrated and filiform antennæ;

ANTHICUS LATERI PUNCTATUS

the maxillary palpi are terminated by a hatchet-shaped joint; and the penultimate joint of the tarsi is bilobed. Some of these species are found upon plants, but the majority live on the ground,

and run with great quickness: their larvae are probably parasites. They compose the genera *Notocus*, *Anthicus*, &c.

ANTHOBIÆ. A section of Coleopterous insects, composed of species inhabiting the southern parts of Europe and the warm parts of both hemispheres. They are distinguished by the two divisions of the lower lip being produced considerably beyond the mentum, and the elytra gaping at the tips, which are rounded; the antennæ have nine or ten joints, the last three composing the club; the terminal lobe of the maxillæ is membranous, silky, and pencil-like, but leathery in others; the upper lip and mandibles are more or less solid, as they are more or less exposed. These insects live upon flowers or leaves.

ANTHOCHÆRA. A genus of birds belonging to the family *Meliphagidæ*, or Honey-eaters, several species of which are found in New Holland. As an example of this interesting genus we give

The **ANTHOCHÆRA MELIVORA**, or **BUSH WATTLE-BIRD**; a bird constantly found where there are Banksias, in New South Wales, South Australia, and Van Diemen's Land. It is bold and spirited, fearlessly attacking and driving away all other birds from the part of the tree on which it is feeding. In spring and summer the male perches on some elevated branch, and screams forth his harsh and peculiar notes,—like a person vomiting,—whence its local

BRSLE WATTLE-BIRD
(*ANTHOCHERA MELLIVORA*)

name *Goo-gear-ruck*, in which the natives have tried to imitate it. While thus employed, it frequently jerks its tail, throws back its head, and distends its throat, as if great exertion were required. It breeds in September and three following months: the nest is round, open, and rather small; it is generally placed in the fork of a small branch, and is formed of fine twigs, lined with fibrous roots. Eggs two, and sometimes three.

Banksias are in blossom the greater part of the year; each flower as it expands is diligently examined by the Wattle-bird, which inserts its long feathery tongue into every part, extracting pollen and insects. It is to be observed that Banksias are not a sign of good land, so that the garrulous note of this species may be taken by the settler as an indication of the sterile and unprofitable nature of the soil. (*Gould's Birds of Australia*.)

ANTHOMYZIDÆ. A general division of the *Muscidae*, composed of species having the appearance of Common Flies; the wings not vibratile; the antennæ inserted near the forehead, always shorter than the head, terminated by a long or linear joint, with the seta mostly plumose; the legs are of moderate size, and the abdomen composed of four joints.

ANTHOPHILA. A name given by Latreille to the fourth family of the Aculeated Hymenoptera (the Bees).

ANTHROCERIDÆ. A family of Lepidopterous Insects, of the section *Heterocera*; comprising a rather numerous group of small or moderately sized species, distinguished by their brilliancy of colour and diurnal flight; having the antennæ never terminated by a pencil of hairs, and either simple in both sexes and fusiform, or thickened near the middle: the head is furnished with a pair of ocelli behind the antennæ; the labial palpi are rather small, and the maxillæ greatly elongated: the wings are always deflexed in repose, exhibiting in many species a number of decuded spots; the nervures are very numerous; the legs are long, with the posterior tibiae furnished with four spurs. The caterpillars are of a cylindrical form, generally clothed with short hairs, and without any spine at the hind part of the body: they feed on various leguminous plants, and con-

siderably resemble those of several of the *Hombycidae*. The pupæ are of the ordinary conical form, without any angular prominences. The colouring of some of the exotic species of this family is truly beautiful. [See *BUNST MOTH*.]

ANTHUS. [See *PIRIT*.]

ANTIPATHES. Black Coral.

ANT-LION. (*Myrmaleon formicaleo*.) A Neuropterous insect which has long been celebrated for its wonderful ingenuity in preparing a kind of pitfall for the destruction of such insects as happen unwarily to enter it. In its complete or fly state it bears no inconsiderable resemblance to a small dragon-fly, from which however it may readily be distinguished by its antennæ, which are hard, and incurvated at the ends. It

ANT LION.—(*MYRMALEON FORMICALEO*.)

deposits its eggs in dry sandy situations, and the young larvæ, when hatched, begin separately to exercise their talent of preparing a very small conical cavity in the sand, which they effect by turning themselves rapidly round. Under this cavity it lies concealed, ready to rush forward at a moment, in order to seize any small insect that has been so unfortunate, in approaching the edge, as to fall in; and no sooner has it sucked out the juices of its victim through its tubercular forceps, than it throws it by a sudden exertion to some distance. As the larva increases in size, it enlarges the hole, which at last becomes about two inches in diameter, its own length being when full-grown about half an inch. It is of a flattened figure, broad towards the upper part, and gradually tapering to an obtuse point: the legs are slender; the head and thorax rather small; the tubular jaws long, curved, serrated internally, and very sharp-pointed: it is of a brown colour, beset with numerous tufts of dusky hair; the whole presenting a form bearing some resemblance to a flat-bodied spider. In preparing its pit, it begins by tracing an exterior circle of the intended diameter of the cavity, continuing its motion, in a spiral line, till it gets to the centre, thus making several volutes in the sand, resembling the impression of a large helix or snail-shell; and after having sufficiently deepened the cavity by a repetition of this motion, it smoothes the sides into a regular shape by throwing out the superfluous sand lying on the ridges, which it effects with surprising address and dexterity.

The ingenuity and perseverance of this insect, or rather the admirable instinct it displays, is so amusingly described by Messrs. Kirby and Spence in their "Introduction to

Entomology." that we cannot refrain from indulging in a quotation, the length of which, we trust, its pertinence may well excuse. "In the course of its labours it frequently meets with small stones: these it places upon its head, one by one, and jerks over the margin of the pit. But sometimes, when near the bottom, a pebble presents itself of a size so large that this process is impossible, its head not being sufficiently broad and strong to bear so great a weight, and the height being too considerable to admit of projecting so large a body to the top. A more impatient labourer would despair; but not so our insect. A new plan is adopted. By a manœuvre, not easily described, it lifts the stone upon its haek, keeps it in a steady position by an alternate motion of the segments which compose that part; and, carefully walking up the ascent with the burthen, deposits it on the outside of the margin. When, as occasionally happens, the stone is round, the labour becomes most difficult and painful. A spectator watching the motions of the ant-lion feels an inexpressible interest in its behalf. He sees it with vast exertion elevate the stone, and begin its arduous retrograde ascent: at every moment the burthen totters to one side or the other: the adroit porter lifts up the segments of its back to balance it, and has already nearly reached the top of the pit, when a stumble or a jolt mocks all its efforts, and the stone tumbles headlong to the bottom. Mortified, but not despairing, the Ant-Lion returns to the charge; again replaces the stone on its back; again ascends the side, and artfully avails himself, for a road, of the channel formed by the falling stone, against the sides of which he can support his load. This time possibly he succeeds; or it may be, as is often the case, the stone again rolls down. When thus unfortunate, our little Sisyphus has been seen six times patiently to renew his attempts, and was at last, as such heroic resolution deserved, successful. It is only after a series of trials have demonstrated the impossibility of succeeding, that our engineer yields to fate, and, quitting his half-excavated pit, begins the formation of another.

"When all obstacles are overcome, and the pit is finished, it presents itself as a conical hole rather more than two inches deep, gradually contracting to a point at the bottom, and about three inches wide at the top. The Ant-lion now takes its station at the bottom of the pit, and, that its gruff appearance may not scare the passengers which approach its den, covers itself with sand, all except the points of its expanded forceps. It is not long before an ant on its travels, fearing no harm, steps upon the margin of the pit, either accidentally or for the purpose of exploring the depth below. Alas! its curiosity is dearly gratified. The faithless sand slides from under its feet; its struggles but hasten its descent; and it is precipitated headlong into the jaws of the concealed devourer. Sometimes, however, it chances that the ant is able to stop itself midway, and with all haste scrambles up again. No sooner does the Ant-lion perceive this (for, being furnished with six eyes

on each side of his head, he is sufficiently sharp-sighted), than, shaking off his inactivity, he hastily shovels loads of sand upon his head, and vigorously throws them up in quick succession upon the escaping insect, which, attacked by such a heavy shower from below, and treading upon so unstable a path, is almost inevitably carried to the bottom. The instant his victim is fairly within reach, the Ant-lion seizes him between his jaws, which are admirable instruments, at the same time hooked for holding and grooved on the inner side, so as to form with the adjoining maxillæ, which move up and down in the groove, a tube for sucking, and at his leisure extracting all the juices of the body, regales upon formic acid. The dry carcass he subsequently jerks out of his den, that it may not encumber him in his future contests, or betray the 'horrid secrets of his prison-house;' and if the sides of the pit have received any damage, he leaves his concealment for a while to repair it; which having done, he resumes his station."

Such is the mode of life pursued by the larva of the Ant-lion until nearly two years have elapsed, when, being arrived at its full growth, and ready to change into a chrysalis, it envelops itself in a round ball of sand, agglutinated and connected by very fine silk, which it draws from a tubular process at the extremity of its body. In this silken cocoon it remains about three weeks; and then bursts forth a four-winged insect, resembling the dragon-fly both in appearance and manners. The Ant-lion is not found in England, but occurs in France, Spain, Germany, &c. (See MYRMELON.)

APATEON. (See SUPPLEMENT.)

APATURA IRIS, or PURPLE EMPEROR. Of all our native Lepidoptera, there is no Butterfly that is more justly admired than the Purple Emperor. In its

PURPLE EMPEROR. — (APATURA IRIS.)

bold and soaring flight, as it displays its beautiful lines in the effulgence of the meridian sun, or as it settles for repose when the shades of evening approach, it still maintains its acknowledged pre-eminence. The general colour of the wings above is a rich deep brown, changing in the male according to the light, to a lovely purple, or a splendid mazarine blue, and relieved by a triple series of white spots. The posterior wings have a white angular band, placed in continuity with the first series of spots on the anterior wings; and an ocellus at the anal angle with a narrow tawny iris and black pupil: the under surface of the anterior wings is a fer-

ruginous brown, varied with white and black; between the disc and the hinder margin is an ocellus with a black iris and a bluish pupil; body black above, cinereous beneath; antennæ black. The female is considerably larger than the male, but the colours are not so deep, nor are the reflected hues so brilliant. The Caterpillar is a bright green, with greenish-yellow horns, reddish at the tip, and has reddish bristles at the tail. It feeds on the oak, ash, and willow. The Chrysalis is of a pale green hue. The perfect insect seldom makes its appearance before July; is by no means scarce; and in various parts of the South and West of England very beautiful specimens are often taken. — There are other species of the genus *Apatura*, but the above is the only one found in Britain.

APE. (*Pithecus*.) The words *Arx*, *Monkey*, and *Baboon* were formerly applied indiscriminately to any of the Quadrumanous Mammalia; it will therefore be right to state, before we proceed further, that the *Arxs*, or *Simiæ*, may be properly divided into four sections; viz. — *Apes*, or such as are destitute of a tail: *Baboons*, or such as have muscular bodies, elongated muzzles, and whose tails are usually short: *Monkeys*, whose tails are in general long; and *Sapajous*, or *Monkeys* with prehensile tails, which can at pleasure be twisted round any object, and thereby in many instances answer the purpose of an additional hand to the animal. It is, however, to the first of these only that our attention is in this place to be directed.

The genus *Ape* (*Pithecus*) comprises those quadrumanous animals which most closely approach to the human species in anatomical structure, and which, in popular language, are termed *monkeys without tails* or *cheek-pouches*. As Buffon justly observes of the whole, they are not quadrupeds, but quadrumana; not four-footed, but four-handed animals. They chiefly inhabit the vast forests of India and Africa, and are numerous in the peninsula of Malacca, and the great islands of the Indian Ocean; living in trees, and feeding on fruits, leaves, and insects; but though frugivorous in a state of nature, yet, from the resemblance of their teeth to those of the human species, it is very evident that their diet may be almost as various as that of Man. They generally live in troops, and some of the species are said to construct a sort of hut of leaves, as a defence against the weather: it is also asserted that they use clubs to defend themselves when attacked.

The Apes are in general fierce and intractable; though some of them appear to be of a grave and gentle disposition; neither petulant nor mischievous, like the monkeys, properly so called. Their arms are so long as almost to touch the ground when the animals stand erect on their hind legs; the fingers and toes are long, flexible, deeply separated from one another, and admirably adapted for prehension: thus they are enabled to spring from tree to tree with surprising agility, even when loaded with their young, who cling closely to them on every appearance of danger. Apes have the power

of assuming a nearly erect position; though on the ground this is by no means convenient, as they stand upon the outer edges, being unable to apply the palms of the posterior hands fairly against the soil, and require a staff, or other support, to maintain this attitude, except when they have been taught to stand erect by man. [See *GORILLA*; *CHIMPANZEE*; *ORANG-OUTANG*; *SIAMANO*; *GIBBON*, &c.]

APHANIPTERA. An order of Apterous Haustellate insects, having rudimental elytra or wings in the perfect state. It is composed entirely of the different species of Fleas, forming the family *PULICIDÆ*; the common Flea (*Pulex irritans*) being the type of the order. The legs are long, the posterior formed for leaping; the coxæ are very large; the fore legs are singularly placed, appearing to arise from the front of the head, the coxæ defending the sides of the rostrum. This peculiarity is caused, by the prothoracic epimera being detached from the body, and extended obliquely beneath the head: the femora are short, but strong; the tibia very setose; and the tarsi five-jointed, terminated by a pair of strong claws. The female flea deposits a dozen eggs, of a white colour, and rather viscous texture, from which are hatched long worm-like grubs, destitute of feet, which are very active in their motions, winding themselves in a serpentine manner through the substance in which they may be deposited: the head of the larva is protected by a firm skin, and bears two antennæ, but no eyes. The body consists of thirteen segments, bearing little tufts of hair, and the last is armed with a pair of small hooks. When full grown, which occurs in summer in about twelve days, the larvæ enclose themselves in a small cocoon of silk, often covered with dust, and attached to adjoining substances: in this it passes into the pupa state, and in about twelve days more emerges a perfect flea.

In hot countries these insects are exceedingly troublesome: but in the West Indies and South America there is an insect belonging to the family having habits different to those of the common flea, which is even still more obnoxious; this is the Chigoe (*Pulex penetrans*), which lives in the open country, and attacks the naked feet both of men and dogs. [See *FLEA* and *CHIGOE*.]

APHIS: APHIDÆ. A genus and family of Homopterous insects, comprising the very numerous and obnoxious species of *Plant-lice*, a tribe of insects analogous, in regard to the vegetable world, to the animal parasites of the order *ACROPLURA*, or lice. The antennæ are of great length; the ocelli, three in number, form a large triangle; the eyes are entire, prominent, and semiglobose; the abdomen is short and convex, generally furnished with a tubercle on each side near the extremity. Some are winged, and some are wingless, without distinction of sex; the wings are very much deflexed at the side of the body, being almost perpendicular in repose; the fore wings much larger than the posterior, with strong nerves: the legs are very long and slender, formed only for

crawling. The species reside in great societies upon almost every species of plant, of which they suck the young shoots, leaves, and stems, by the assistance of their proboscis, producing disease in the plant either by greatly weakening it, or by raising vesicles, or other gall-like excrescences, in which whole generations of Aphides reside. The anal tubercles above mentioned secrete a saccharine fluid of which ants are very fond; and it is this fluid dropped upon the adjacent leaves, or the extravasated sap flowing from the wounds caused by the punctures of the insects, which is known under the name of the *honey-dew*. In the spring they are viviparous, in the autumn and as winter approaches they are oviparous; and by a surprising aberration from the common laws of nature, it appears that one impregnation of the female is sufficient for many generations, without further assistance from the male. All the Aphides which appear in the spring are exclusively females, no males being found till the autumn; and the females are endowed with such astonishing fecundity, that nine generations—each generation averaging 100 individuals—have been produced within three months; “so that from a single Aphid, 10,000 million millions may be generated in that short period!” In some years they are so nume-

PLANT-LICE.—(APHIS PLATANOIDEUS.)

rous as to cause almost a total failure of the hop plantations; at other times the beans, peas, and potatoes are injured by them to an alarming extent; as also are numerous shrubs, and plants, including the delicate exotics raised in stoves and green-houses. There are numerous species; uniformly deriving their specific name from the tree, shrub, or plant, on which they are commonly found. Of these the *Aphis rapae*, which has made a great noise as the *Aphis vastator* and feeds on various plants, the *Aphis roseæ* (or rose louse), the *Aphis humuli* (or hop-fly), and the *Aphis vitis* (or vine-fretter), are among the best known and most destructive; but the largest and most remarkable of the British Aphides is the *Aphis salicis*, which is found on the different kinds of willows, and is nearly a quarter of an inch long. Many of the species have the body densely clothed with a white cottony secretion, either in threads or flakes; among these may be particularly mentioned the *Aphis*

lanigera, or *American blight*, as it is termed, which infests the stems of Apple-trees, sometimes totally destroying them.

“The injuries occasioned by plant lice,” as Dr. Harris very truly observes, “are much greater than would at first sight be expected from the small size and extreme weakness of the insects; but these make up by their numbers what they want in strength individually, and thus become formidable enemies to vegetation. By their punctures, and the quantity of sap which they draw from the leaves, the functions of these important organs are deranged or interrupted, the food of the plant, which is there elaborated to nourish the stem and mature the fruit, is withdrawn before it can reach its proper destination, or is contaminated and left in a state unfitted to supply the wants of vegetation. Plants are differently affected by these insects. Some wither and cease to grow, their leaves and stems put on a sickly appearance and soon die from exhaustion. Others, though not killed, are greatly impeded in their growth, and their tender parts, which are attacked, become stunted, curled, or warped. The punctures of these lice seem to poison some plants, and affect others in a most singular manner, producing warts or swellings, which are sometimes solid and sometimes hollow, and contain in their interior a swarm of lice, the descendants of a single individual, whose punctures were the original cause of the tumor. I have seen reddish tumors of this kind, as big as a pigeon’s egg, growing upon leaves, to which they were attached by a slender neck, and containing thousands of small lice in their interior. Naturalists call these tumors galls, because they seem to be formed in the same way as the oak-galls which are used in the making of ink. The lice which inhabit or produce them generally differ from the others, in having shorter antennae, being without honey-tubes, and infrequently being clothed with a kind of white down, which, however, disappears when the insects become winged.”

Mr. Knapp, in his ‘Journal of a Naturalist,’ has thus described this species, and its effects. “Our apple-trees here are greatly injured, and some annually destroyed, by the agency of what seems to be a very feeble insect. We call it, from habit, or from some unassigned cause, the ‘American blight.’ [It seems, however, that it had been noticed in England as early as the year 1787; and there is good reason to believe that in America it is not indigenous, but was introduced there with fruit-trees from Europe.] In the spring of the year a slight hoariness is observed upon the branches of certain species of our orchard fruit. As the season advances this hoariness increases, it becomes cottony; or, in other words, towards the end of summer the under sides of some of the branches are invested with a thick, downy substance, so long as at times to be sensibly agitated by the air. Upon examining this substance, we find that it conceals a multitude of small wingless creatures, which are busily employed in preying upon the limb of the tree beneath. This they are well enabled to do, by means of a beak termina-

ting in a fine bristle; this, being insinuated through the bark and the sappy part of the wood, enables the creature to extract, as with a syringe, the sweet, vital liquor that circulates in the plant. The albumen, or sap-wood, being thus wounded, rises up in excrescences and nodes all over the branch, and deforms it; the limb, deprived of its nutriment, grows sickly; the leaves turn yellow, and the part perishes. Branch after branch is thus assailed, until they all become leafless, and the tree dies." * * * * *

"Many remedies have been proposed for removing this evil, efficacious perhaps, in some cases upon a small scale; but when the injury has existed for some time, and extended its influence over the parts of a large tree, I apprehend it will take its course, and the tree die."

Upon this part of the subject, Dr. Harris remarks that the application of the spirits of tar, of spirits of turpentine, of oil, urine, and of soft soap, has been recommended; but he is inclined to think that the following mode of treatment will be found the most effectual of any: "Scrape off all the rough bark of the infected trees, and make them perfectly clean and smooth early in the spring; then rub the trunk and limbs with a stiff brush wet with a solution of potash; after which remove the sods and earth around the bottom of the trunk, and with the scraper, brush, and alkaline liquor cleanse that part as far as the roots can conveniently be uncovered. The earth and sods should immediately be carried away, fresh loam should be placed around the roots, and all cracks and wounds should be filled with grafting cement or clay mortar. Small limbs and extremities of branches, if infected, and beyond reach of the applications, should be cut off and burned." He further observes, in reference to remedial measures necessary to counteract the injury done to plants generally by the different species of Aphides, that "solutions of soap, or a mixture of soap-suds and tobacco water, used warm and applied with a watering-pot or with a garden-engine, may be employed for the destruction of these insects. It is said that hot water may also be employed for the same purpose with safety and success. The water, tobacco-tea, or suds should be thrown upon the plants with considerable force, and if they are of the cabbage or lettuce kind, or other plants whose leaves are to be used as food, they should subsequently be drenched thoroughly with pure water. Lice on the extremities of branches may be killed by bending over the branches and holding them for several minutes in warm and strong soap-suds. Lice multiply much faster, and are more injurious to plants, in a dry than in a wet atmosphere; hence in green-houses, attention should be paid to keep the air sufficiently moist; and the lice are readily killed by fumigations with tobacco or with sulphur. To destroy subterranean lice on the roots of plants I have found that watering with salt-water was useful, if the plants were hardy; but tender herbaceous plants cannot be treated in this way, but may sometimes be revived by frequent watering with soap-suds."

The species of this family are greatly subject to the attacks of other insects; the larvae of the *Hemicrobiidae*, the *Coccinellæ*, and the larvae of various species of *Syrphidae* feed upon them, and destroy vast numbers; they are also infested by minute parasitic Hymenoptera belonging to the families *Cyrtipidae*, *Ichneumonidae*, &c. In the papers of Mr. F. Walker, F.L.S., and in his Catalogue of the species in the British Museum, much information on the British Aphides is given.

APHIDIPHAGI. The name of a family of Coleopterous insects, which are for the most part of a hemispherical form, and compose the genus *Coccinella* (or Lady-birds).

APHODIÆ. A family of minute Lamellicorn beetles, extremely abundant in this and other temperate countries, especially during the spring months, swarming in the dung of the larger herbivorous animals, or hovering over it as soon as it is dropped. The body is of an oblong or oval shape, rounded at the extremity, with the abdomen entirely concealed by the elytra: they are nearly allied to the *Scarabæidæ*, both in their antennæ, organs of the mouth, and legs, but the body is more elongated.

APHRODITA, or SEA-MOUSE. A small

marine annelide, known on our coasts as the Sea-mouse. Its figure is oval and annelated; and it is covered with a large quantity of silky hairs of

a very bright metallic lustre, the colours of which vary with the play of the light. On the back are two rows of large membranous scales, which somewhat resemble the elytra of insects. In many species the lateral setæ or bristles exhibit a beautiful structure, being barbed on each side of the tips, and each of these barbed setæ being inclosed in a smooth horny sheath. It not unfrequently happens that a large number of Aphrodites are thrown up on the British shores after a gale of wind.

APHROPHORA. A genus of Homopterous insects which in the larva state live on plants enveloped in a saliva-like mass; whence their popular name of *Cuckoo-spits*; the insects in their perfect state are named from their leaping powers, *Frog-hoppers*. [See *CICADA*.]

APIDÆ. An extensive family of Bees, which may be classed under three heads; namely, 1. Social bees; 2. Solitary working bees; 3. Cuckoo-like parasitic bees. The insects composing this family are distinguished by having the mentum long, with the labium at its extremity, forming an elongated slender seta, with two small lateral filaments, and forming with the maxillæ an elongated proboscis, capable of being projected in front of the head when in action, or folded up beneath it and the breast when at rest. The antennæ are often elbowed, the basal joint being long. Following the

arrangement compiled by Mr. Westwood, we find the *APIDE* are divided into five sub-families:—

1. *PANURGIDÆ*, consisting of insects nearly allied to the *Andrenidæ* in the labium being shorter than the mentum, and the structure of the labial palpi, which are composed of continuous linear joints, the two basal ones not being so much elongated as in the following sub-families. The maxillary palpi are six-jointed; the upper lip is short; and the females are destitute of a pollen brush on the under surface of the abdomen. They are, however, furnished with a pollen plate on each side of the metathorax, and another on the posterior femora: the hind legs have also pollen brushes. Nothing is known of their nidification; but Latreille observes that the perfect insects of the genus *Panurgus* are attached to semi-florescent flowers.

2. *DENTATE, or MELECTIDÆ*. The insects composing the second sub-family (as well as those of all the following sub-families of bees) have the labial palpi formed of two very long, flattened, scaly basal joints, and two minute apical ones. The abdomen is not provided with a ventral pollen brush, neither do these insects possess any pollen plates, their bodies being in effect naked, whence they are supposed to be parasites. Some of the species resemble small wasps in their colours, whilst in others some parts of their bodies are clothed with small patches of very short hairs. From their evidently parasitic habits they have been termed Cuckoo-bees.

3. *LONGILABRES, or MEGACHILIDÆ*. The third sub-family of the *Apidae*; composed of insects distinguished by the large oblong form of the upper lip, and strong mandibles: the maxillary palpi are but slightly developed; while on the contrary, the labial are very long, with the two last joints obliquely inserted. Nearly all the genera are polliniferous, the pollen brush being very large, and covering the under side of the abdomen: they are, however, destitute of pollen plates. "From their respective economy, they have been termed Mason and Upholsterer bees; the former building their nests of fine moistened earth, whilst the Upholsterers employ in the construction of their cells portions of leaves which they have cut from various plants by means of their powerful jaws, which are employed like a pair of scissors." Some of the species of the genus *Osmia* construct their nests of minute grains of sand, cemented together with a glutinous secretion, and which are placed by the insects on the angle of a wall, the crevices between bricks, &c. The genus *Megachile* comprises the Leaf-cutting and some other bees. These form their nests in the trunks of decayed trees, and in old rotten palings. They are lined with pieces of leaves, of a circular form, which the insects have most dexterously clipped off, and afterwards adjusted together so admirably, that, although not covered with any coating of gum, &c., they are honey-tight.

4. *SCORULIDÆ*. This sub-family derives its name from the very thick coating of hairs upon the hind legs of the females, which

constitute the pollen brushes. The wings have commonly three perfect submarginal cells; the third joint of the antennæ is often long and clavate, and the mouth is occasionally very considerably developed. Notwithstanding the shortness of the wings, and the robustness of the body, these insects fly with great strength and rapidity, making a loud humming noise. They nidificate in the crevices of old walls or in the ground, preferring banks exposed to the sun.

"We are indebted to Reaumur," as this gentleman observes, "for the history of the Carpenter bees, *Xylocopa*, a genus containing the largest species of the family, all of which are exotic. Their wings are often black, with a fine purple or violet gloss, and some of the species are richly coloured. The females of *Xylocopa violacea* appear in the spring, and select posts, paliogs, espaliers, &c. in gardens, in which they construct their burrows, from twelve to fifteen inches in length, and rather more than half an inch in diameter; the top and bottom of the tunnel is curved, having a passage at each end. When completed, they deposit an egg at the bottom, with a proper supply of pollen paste; the whole is then covered with a layer of agglutinated sawdust, formed during the construction of the burrow: the layer thus formed serves not only as the roof of one cell, but as the floor of another which is placed immediately above it. They thus proceed till about a dozen cells are formed. When the larvæ are full grown, they assume the pupa state, head downward, so as to allow the lowermost and oldest to make its way out of the bottom of the burrow as soon as it becomes winged, and which consequently takes place earlier than in those which occupy the upper cells."

5. *SOCIATES*. The fifth and last sub-family of the *Apidae*. "Here, dependent upon their social habits, we find each species composed of three kinds of individuals; viz. males, females, and nenters, or workers. In addition to their gregarious habits, the circumstances of the larvæ being fed from time to time by the worker bees, and the cells being generally of an hexagonal form, they are also distinguished by their peculiar habit of secreting wax for the manufacture of the cells of their nests. In these insects, the outside of the posterior dilated tibia is smooth, and hollowed in the neuters into a shining plate, for the reception and carrying of pollen, which has been accumulated by means of the pollen brushes upon the basal joint of the tarsi of this pair of legs. The maxillary palpi are minute and exarticulate. These bees have the body covered with thick hairs."

"The Humble-bees, composing the genus *Bombus*, are at once known by their large and very hairy bodies: they are the largest species of the *Mellifera* found in England; and they are often of a black colour, with bands of yellow or orange. They form societies consisting of about fifty or sixty individuals, occasionally, however, amounting to two or three hundred. They construct their dwellings under ground, in meadows, pastures, or hedge-rows, generally employ-

ing moss for this purpose. Their union, however, lasts only till the cold weather kills the great mass of the inhabitants, a few impregnated females alone surviving to become the foundresses of fresh colonies at the commencement of the following spring. The neuters are late in their appearance, being produced from eggs produced by these foundress bees; and it is not till autumn that the males appear. Unlike the hive-bees, the females take their share in the labours of the community, and they are accordingly furnished with two peculiar organs possessed by the neuters, of which the queen of the hive is destitute, although the neuters of the latter insect possess them; namely, the dense fringe of hairs surrounding the pollen-plate of the posterior tibia, and the dilated base of the first tarsal joint. The economy of the humble-bee also, unlike that of the hive, admits of the presence of numerous females in the same nest. The species of *Bombus* are very difficult to determine, from the colours of the hairs being very liable to fade. It is essential, therefore, to trace the insects from their first leaving the nest."

The Hive-bee, and some other analogous species (forming the second section of the *Societes*), have the basal joint of the posterior tarsi striated, and the posterior tibia have no spurs at the extremity, a character not to be found in any other Hymenopterous group. * * * The principal species of bees kept for domestic purposes are the following:—*Apis mellifica* (Linn.), or the common hive-bee of Europe, and which has also been introduced into the U. S. of America and into New Zealand; *Apis ligustica* (Spinola), kept in some parts of Italy; *Apis fasciata* (Lat.), in Egypt and some parts of Asia Minor; *Apis unicolor* (Fab.), in Madagascar; *Apis Indica* (Linn.), at Bengal; *Apis Adansonii* (Latr.), at Senegal. Lacordaire also observed hives of an undescribed species of Chili; and the Horticultural Society of London, in 1825, received a hive of bees from New Holland, differing materially from the bees of Europe, "being infinitely smaller and wholly without stings." An interesting work on the British Bees, by Mr. Frederick Smith, may be shortly expected; in the "Zoologist," &c. he has published much on the subject.

APLON FROM MONTANUM.

more than one tenth of an inch long, exclusive of the slender sharp-pointed snout. Its

grubs live in the pods of the common wild indigo bush, *Baptisia tinctoria*, devouring the seeds. A smaller kind, somewhat like it, inhabits the pods and eats the seeds of the locust-tree, or *Robinia pseudacacia*.—Harris.

APLYSIA. A genus of *Tectibranchiate* Mollusca, of which several species are known. The body of the animal consists of a soft fleshy mass; it has four flattened tentacular appendages; the mouth in the form of a vertical fissure, with two lateral labial plates, and a cordiform tongue beset with denticles; branchium covered by a sort of operculum; and shell wanting. From the borders of the mantle is poured out abundantly a deep purple liquor, with which the animal colours the water around to a considerable distance, when it perceives any danger. The *Aplysia depilans*, or Depilatory Aplysia, is found in the European seas adhering to rocks; it is extremely fetid, and it was long supposed that the acrid humour which it exuded occasioned the loss of the hair. Its digestive apparatus consists of a membranous crop, of enormous size, which leads into a muscular gizzard, furnished with pyramidal cartilaginous teeth; and a third stomach beset with pointed hooks; besides a fourth sacculus. Its general colour is blackish, with grey or brown blotches, and tinged with purple. The ova is laid in long glairy entangled filaments, as slender as threads.

APODES or APODA. An order of fishes characterised by Linnaeus as being composed of all those which are destitute of ventral fins. According to Cuvier's system, however, they must not only want ventral fins, but be likewise malneopterygious. Of this kind a good and familiar example is seen in the common Eel.

APOLLO [BUTTERFLY]. [See *PAR-NASSIUS*.]

APOSURE. The name given to a section of the Nocturnal Lepidoptera, differing from all the rest of the order in the caterpillars being destitute of any anal feet, the extremity of the body terminating in a point, which in many is forked, or furnished with two long articulated appendages, forming a kind of tail.

APPLE-MOTH. [See *TONTRIX*.]

ASPIDOPHORUS. The Armed Bullhead or Pogge. [See *BULLHEAD*.]

APTENODYTES. The generic appellation of the curiously-formed palmapied birds, known by the name of *Penguins*, a more general and detailed account of which will be found under the letter P. In this place we shall merely make an extract from Capt. Sir J. C. Ross's Voyage to the Antarctic Regions, where he speaks of the Great Penguins: "These enormous birds varied in weight from sixty to seventy-five pounds. The largest was killed by the Terror's people, and weighed seventy-eight pounds. They are remarkably stupid, and you are able to approach them so near as to allow you to strike them on the head with a bludgeon, and sometimes, if knocked off the ice into

the water, they will almost immediately leap upon it again as if to attack you, but without the smallest means either of offence or defence. They were first discovered during Capt. Cook's voyage to these regions, and the beautiful unpublished drawing of Forster the naturalist has supplied the only figures and accounts which have been given to the public, both by British and foreign writers on natural history. Mr. G. R. Gray has therefore named it in the zoology of our voyage, *Aptenodytes Forsteri*, of which we were fortunate in bringing the first perfect specimens to England. Some of these were preserved entire in casks of strong pickle, that the physiologist and comparative anatomist might have an opportunity of thoroughly examining the structure of this wonderful creature. Its principal food consists of various species of *canceri* and other crustaceous animals; and in its stomach we frequently found from two to ten pounds weight of pebbles, consisting of granite, quartz, and trappean rocks. Its capture afforded great amusement to our people, for when alarmed and endeavouring to escape, it makes its way over deep snow faster than they could follow it; by lying down on its belly and impelling itself by its powerful feet, it slides along upon the surface of the snow at a great pace, steadying itself by extending its fin-like wings, which alternately touch the ground on the side opposite to the propelling leg."

In No. IV. of the Appendix to the work above quoted, (the Geology of the Southern Islands, by R. Mc Cormick, Esq.,) the writer observes: "As I had no opportunity of landing for specimens, I was in the habit of examining the stomachs of most of the birds which I shot and preserved for the Government Collection; and found the Penguins my best geological collectors, for their crops were frequently filled with pebbles; more especially the large species, *Aptenodytes antarctica*. In one of these individuals I found upwards of a pound of small fragments of rocks; comprising basalt, greenstone, porphyry, granite, vesicular lava, quartz, scoria, and pumice; but none of them ever brought me a vestige of aqueous rocks,—all were volcanic,—and such the appearance of the Antarctic lands, even at a distance, would proclaim them to be. We saw three

ANTARCTIC PENGUIN.
(*APTENODYTES ANTARCTICA*.)

species of Penguins within the Antarctic circle. The larger kind, '*Aptenodytes antarctica*,' attains a great size. I preserved one, weighing seventy-five pounds. It is a scarce bird, generally met with singly; and

I have never seen more than two or three together; whilst the two smaller species congregate in vast numbers. I know not to what cause we can assign this very remarkable paucity of individuals in the larger species."

APTERA. An order of the Linnæan class *Insecta*; characterized, as the term implies, by having no wings in either sex. It includes the modern orders *Crustacea*, *Arachnida*, and *Myriapoda*.

APTERYX. A bird which in form somewhat resembles a Penguin, and stands about two feet in height. The beak is very long, slender, marked on each side with a longitudinal groove, and furnished with a membrane at its base. Its wings are simple rudiments; a mere stump, terminated by a hook. It has no abdominal air cells, nor are any of its bones hollow. The feathers have no accessory plume, but fall loosely, like those of the emu, and their shafts are prolonged considerably beyond the base.

WINGLESS EMU.—(*APTERYX AUSTRALIS*.)

The feet have a short and elevated hind-toe, the claw of which is alone externally visible. The eye is small, and a number of bristle-like hairs surround the mouth. Its colour is deep brown; its time of action nocturnal; and it subsists on insects. It runs with rapidity, the limbs are extremely powerful, and it defends itself vigorously with its feet. This bird is chiefly met with in the southern parts of the interior of New Zealand. When chased, it takes refuge in the clefts of rocks, hollow trees, or in deep holes which it excavates in the ground; and it runs with great swiftness, with its head elevated like the ostrich. The natives value it greatly for the sake of its skin, which, prepared with the feathers on, they make into dresses. The name given to this bird by the New Zealanders is *Kiwi*. A second species of this curious genus has been lately received by Mr. Gould from the South Seas.

APUS. A genus of small Crustaceous animals which inhabit ditches, lakes, and standing waters, generally in innumerable quantities. They often swarm in myriads, and, indeed, have been known to be carried up by violent storms of wind, and scattered over the land; hence they often appear suddenly in puddles of rain water where none have been previously, especially in

the spring and early in summer. They swim well on the back, and when they hurrow in the sand they raise their tails in the

APUS PRODUCTUS

water. Their food principally consists of tadpoles. When first hatched they have only one eye, four oar-like legs, with whorls of hairs, the second pair being the largest: the body has then no tail, and the shell only covers the front half of the body: the other organs are gradually developed during succeeding moultings. These creatures are the common food of the Wagtails. We give the species *Apus productus* as an example.

AQUILA. [See EAGLE.]

ARACHNIDA. A class of Artienlated animals, including Spiders, Mites, and Scorpions, all ranked by Linnæus under Insects; but though having a great analogy with them, and being equally fitted to live in the air, are distinguished from them by their number of limbs, their internal structure, and habits. All the Arachnida are destitute of antennæ, and have the head united with the thorax: they have generally eight legs, though some species have six, and others ten; they have no wings; most of them breathe by means of air-sacs, instead of by prolonged tracheæ; and in the greater part there is a complete circulatory system. Most of the Arachnida are carnivorous, and are furnished with appropriate organs for their predatory life; but in general they confine themselves to sucking the juices of insects; and in order to enable them to capture and subdue animals otherwise capable of effectual resistance, Nature has furnished them with a poisonous apparatus. [See SPIDER.]

ARACARI (Pteroglossus.) A genus of birds, which, like the Toucans breed in the hollows of decayed trees, which they enlarge and render commodious by means of the beak; and it is from this habit that the Brazilians give them the name of *Tacatoca*, in imitation of the sound made by clipping the decayed wood. We may here mention two species described and figured in Mr. Gould's truly elegant monograph of the Toucans.

ARACARI TOUCAN. (Pteroglossus pluripectus.) This bird, as depicted and described by Mr. Gould, is twenty inches in length, of which the bill is four inches and a half; a broad band of black advances from the nostrils along the whole of the culmen, and forms a narrow belt down the sides of the upper mandible at its base; the elevated basal margin of the bill is yellow; the sides of the upper mandible beautiful orange-yellow, fading into yellowish white towards the tip; under mandible wholly black, with a yellow basal ridge; head, neck, and chest black; the whole of the upper surface, except

the rump, which is scarlet, dark olive green; breast marked with two broad bands of black, the upper separated from the throat by an intervening space of yellow dashed with red; a similar but broader space separates the two bands of black, the lower of which is bounded by scarlet, advancing as far as the thighs, which are brownish olive; under the tail coverts light yellow; naked space round the eyes; tarsi and feet dark lead-colour. It is a native of Brazil.

THE CURL-CRESTED ARACARI (Pteroglossus ulocomus), is one of the most rare and beautiful of its tribe. Its length from the tip of the bill to the end of its tail is eighteen inches: the crown of the head is covered with an elegant crest of curled feathers without barbs, which are of an intense glossy black, but as they approach the occiput they become straight, narrow, and spatulate; the feathers on the cheeks are of a yellowish white colour, tipped with black; the hack of the head and upper tail coverts are of a deep hood-red; the breast is a delicate yellow, with slight crescent-shaped bars of red; the hack, tail, and thighs are olive green; the quills brown, the tarsi lead-coloured; the beak of this species is lengthened, both mandibles being edged with thickly-set white serratures; the upper has an orange-coloured culmen, bordered by a stripe of dull blue extending nearly to the tip, below which, the sides of the mandibles are fine orange-red; the under mandibles are straw colour, becoming orange at the tip, and a narrow band of rich chestnut encircles both mandibles at the base. During life the colouring of the bills is generally very vivid; but after death the bright hues fade, so as often-times to become nearly obsolete.

ARACHNOTHERES, or SPIDER-CATCHERS. Small birds, very similar to the Sun-birds in respect to their long, arcuated beak: they inhabit the Indian Archipelago, and live on spiders.

ARANEA. [See SPIDER.]

ARCA, or ARK SHELL. The *Arcula*, a family of Bivalve Shells, found in the Atlantic and Pacific Oceans, the Mediterranean, &c., are distinguished by their great number of teeth, resembling those of a fine saw, and forming either a straight or curved continuous line. They bury in the sand near the coasts, and are also sometimes found attached to rocks, coral, &c. The *Arca* is nearly equivalve, inequilateral, heart-shaped, valves ribbed, and in some species gaping at the lower part. A few have one valve larger than the other; and many have a velvety or shelly epidermis, frequently ending in a deep fringe.

ARCHEGOSAURUS. [See APATEON in SUPPLEMENT.]

ARCHER-FISH. [See TOXOTUS.]

ARCHES. A name given to Moths of the genera *Pelia* and *Xylophasia*.

ARCTIA CAJA. There are few more striking insects among the night-flying Lepidoptera than *Arctia*, or Tiger Moths. The one we have here selected is well known and

abundant. It measures from two and a half to three inches in the expanse of the fore wings, which are of a rich brown colour, with numerous irregular spots and streaks of cream white; the hind wings bright red, with blue-black spots; the thorax brown, with a red neck-band, and the abdomen red, with blue-black bars. The insects belonging to this genus are observed to vary consider-

TIGER MOTHE.—(ARCTIA CAJA.)

ably in their markings, and the present species is no exception to the general rule; some having the brown and blue-black portions more or less obliterated, whilst in others they are sometimes almost entirely predominant. The Caterpillar is dark brown, and very hairy, the hairs on the back dusky, and those on the neck and sides reddish, the head black: its food is nettles, chickweed, lettuce, strawberries, &c. When full fed it spins itself a web, wherein, at the latter end of April, it changes to the Chrysalis state; and the Moth appears about the end of June or beginning of July.

CATERPILLAR OF ARCTIA CAJA

ARCTIC FOX. (*Vulpes lagopus*.) A small species of Fox, inhabiting the high northern latitudes, and justly celebrated for the beauty and fineness of its fur. [See Fox.]

ARCTIIDÆ. A family of Lepidopterous insects, belonging to the general section **HETEROCERA**, comprising those species which have the wings deflexed in repose, the posterior pair not extending beyond the costa of the anterior. The antennæ of the males are strongly serrated; the spiral tongue is either very small, or obsolete; and the labial palpi are generally short and obtuse at the tip. The caterpillars vary much: in some species they are thickly hairy; some are furnished with long fascicles of hairs; and some are naked, but variously tubercled.

They feed upon the external parts of plants, and enclose themselves in cocoons when about to undergo their transformations. The types of the family are distinguished by their larvæ being very thickly clothed with long hairs, whence they have obtained the name of "woolly bears." Such are especially the larvæ of the various species of Tiger Moths, and others nearly allied to them, which are well known, and considered as being amongst the most beautiful of all the species of Moths; their fore wings are ornamented with white, brown, or black, and the hind wings red, with black or blue markings. Some of these caterpillars are extremely destructive, particularly to fruit trees and hedges. Great alarm has been created at times when they were particularly abundant; and, indeed, their polyphagous habits on such occasions may justly be dreaded. The larvæ of some species are furnished, in addition to the long slender hairs all over the body, with several short, thick, truncated tufts of hair on the back as well as at the sides; the majority of these produce species not materially differing in the sexes; but some, forming the genus *Orygia*, have females with the smallest rudiments of wings, and large swollen abdomens, and which are exceedingly sluggish in their habits, whilst the males are constantly on the wing, sitting about in the hottest weather of autumn. The family likewise comprises several other genera differing widely in the appearance of the sexes, or anomalous as respects their transformations.

ARCTOCEPHALUS URSINUS. The Urinal; a species of Seal, from the north of the Pacific Ocean. It is eight feet long, has no mane, and varies in colour from brown to whitish. [See SEAL.]

ARCTOMYS. [See MARMOT.]

ARCUATA. A section of the genus Cancer, of which the true Crabs are the type. [See CRAB.]

ARDEA. The Heron (which see).

ARDEIDÆ. A very extensive family of birds, formed for wading, and generally seeking their food on the margins of rivers and lakes, and in marshes, where they obtain fish, reptiles, and even small mammalia. They are characterized by having very long legs, with a strong, straight, pointed, and compressed bill; in most species finely toothed; the upper mandible usually notched towards the tip; a furrow passing from the nostrils, which are linear, to the apex. They in general build and breed in societies, but always wander alone in search of food, and after the breeding season lead a solitary existence. They have ample wings, and many of them are adorned with elegant plumes and crests. [See HERON, STORK, &c.]

ARENICOLA. A genus of *Dorsibranchiata*, or Cuvier's second order of the class *ANNELIDA*. The gills are of an arborescent form, on the rings of the middle part of the body. The best known species (*Arenicola marina*) is common on our coasts, where the fishermen, who dig for it as bait, know it by the name of the Lob-worm. It is almost a foot

loog; the body is of a reddish colour; and on being touched, exudes a quantity of yellow fluid. The animal bores for itself a passage through the sand, and secures the sides of the passage from falling in by applying to them a glutinous cement, which unites the particles of sand into a kind of wall or coating. This covering does not adhere to the body, but forms a detached tube, within which the animal moves with perfect freedom, and which it leaves behind it as it progressively advances; so that the passage is kept pervious throughout its whole length, by means of the lining, which may not inaptly be compared to the brickwork of the shaft of a mine or tunnel.

ARENICOLI. The name given to a section of beetles which live in dung, and form deep burrows in the earth. The elytra entirely cover the abdomen; the mandibles are horny, exposed, and curved; the terminal lobe of the maxillæ is generally straight; and the antennæ are ten or eleven-jointed. They fly about in the twilight after sunset, and counterfeit death when alarmed.

ARGALL. A species of wild Sheep, found on the mountains of Siberia and Kamtschatka. It so closely resembles the Mouflon [which see] as to be regarded by many naturalists as the same species.

ARGENTINE. (*Argentina sphyreæna*.) A genus of Malacoptyergious fish, belonging to the *Salmonidæ*; the mouth of which is small and toothless; the tongue is furnished with strong hooked teeth; and the digestive organs resemble those of the Trout. The well-known species *Argentina sphyreæna* is caught in the Mediterranean, and is common in the markets of Rome: it has also, though very rarely, been caught on the British coast. It is about two inches and a half in length; the eyes are large, and the irides silvery; the lower jaw much sloped; the teeth small; the body compressed, and of an equal depth almost to the anal fin; and the tail forked. The back is of a dusky green; the sides and covers of the gills appear as if overlaid with silver; on each side of the belly is a row of circular punctures, and above them another which terminates near the vent. The air-bladder is thick, and loaded with *mare*, the substance used in making artificial pearls.

ARGONAUT, or PAPER-NAUTILUS. A curious molluscous animal, the shell of which is peculiarly white and delicate: not chambered, as in the true Nautilus, but possessing one spiral cavity, into which the animal can withdraw itself entirely. It has eight arms, two of which expand into wide membranous flaps; and as the animal floats on the surface of the sea, the expanded membranes are spread over the sides of the shell, where, meeting along its keel or edge, they are said to be held in close contact by a double row of suckers, and thus completely inclose it. Such being the structure and action of the Argonauts, it is not surprising that it has had the reputation, from very early times, of using its arms as oars, and spreading these expanded membranes as

sails, so as to be wafted along by the wind. [See NAUTILUS.]

The nature and habits of the Argonauts having long been a subject of much controversy, a lady (Madame Jeannette Power) made a series of interesting experiments, in 1836, the result of which she laid before the Academy at Catania. In order to arrive at her conclusions, she had cages constructed, and placed in a shallow part of the sea, near the citadel of Messina, and in these cages she inclosed several of the living animals, which she kept supplied with small molluscs, their natural food. The result of her observations went to prove that the animal is in the habit of sailing on the water, using its dilated tentacula as sails, the remainder as oars, and aiding its movements by means of a kind of proboscis which it employs as a helm. The sail, when spread out, presents a silvery surface, speckled with concentric circles of spots, with a black spot in the middle, surrounded with a beautiful gold colour. The animal is not attached to the shell, but, when under water, it adheres firmly to it by its sail-arms. The shell, which is remarkably brittle when exposed to the air, is quite pliable in water, and thus escapes the destruction to which so thin and tender a fabric would otherwise be liable. The animal at the approach of any object takes in its tentacula, wraps its sails over the shell, and descends, blackening the water at the same time, if hard pressed, by a discharge of inky fluid, to cover its escape.

ARGONAUT, AND SAIL.

ARGULUS. A genus of Crustaceous animals, belonging to the *Panctopoda*. The best known species, *Argulus foliaceus*, is found in this country. This aquatic parasite attaches itself to the young of Frogs, Sticklebacks, &c., and sucks their blood: it is also found upon the Perch, Pike, Carp, and Trout. The body is flattened; of a greenish-yellow colour; less than a quarter of an inch long; and is divided into five somewhat indistinct segments along the back. The animal turns itself about in the water in a similar manner to the *Gyrini*. The eggs are oval, of a milky white colour, and are attached by gluten to stones or other hard substances; and before the Argulus arrives at the adult state it undergoes several transformations.

ARGUS-PHEASANT. (*Argus pigantæus*.) This beautiful but rare bird is a native of

many parts of the Indian Islands. The male measures five feet six or eight inches from the beak to the tip of the tail; and the whole of the plumage is remarkable for variety and elegance. The wings consist of very large feathers, nearly three feet long, the outer webs being adorned with a row of large eyes (ocelli), arranged parallel to the shaft; the tail is composed of twelve feathers,

ARGUS PHEASANT.—(ARGUS GIGANTEUS.)

the two middle ones being about four feet in length, the next scarcely two, and gradually shortening to the outer ones. The whole plumage is, indeed, so varied, that to attempt to describe it fully in our limits would be vain. Its voice is rather plaintive, and not harsh as in the peacock. It is considered a very shy bird, but one was kept alive a considerable time in the aviary of the Zoological Gardens, where the pleasing variety of its plumage and the beautifully coloured skin of its head were much admired.

ARGUS. [See PECTEN.]

ARGYNNIS. A genus of diurnal Lepidoptera. We here describe two beautiful British species of Butterflies belonging to this division.

ARGYNNIS PAPHIA, or SILVER STREAK BUTTERFLY. There are few of the Lepidoptera more abundant in the woods and meadows of the South of England than the Silver Streak, which is known to

SILVER-STREAK BUTTERFLY.—(A. PAPHIA.)

delight in settling on the bramble-blossoms. In the male the wings above are fulvous, in the female virrescent, with numerous longitudinal and transverse black lines and bars, and three rows of marginal black spots; anterior wings beneath, paler and less spotted; the posterior wings are greenish beneath, with four irregular narrow pale silvery-waved bands; between the two last is a series of ocelli, with a green iris and pale pupil, and on the margin is a row of green crescents: the cilia of all the wings above are fulvous and black, paler and ferruginous beneath: the body fulvous above, grayish beneath: the antennæ are brownish, with the club black.

ARGYNNIS LATHONIA, or QUEEN OF SPAIN FRITILLARY. This exceedingly beautiful species, though rare in this country, appears to be very common on

QUEEN OF SPAIN BUTTERFLY
(ARGYNNIS LATHONIA.)

the Continent. The upper surface in general markings resembles that of the allied species, but it may be at once known by the beautiful and well-defined silver marks on the under surface of the lower wings. British specimens of it are much prized by the collector. Our cuts will give a very good idea of this insect, as we have figured both the upper and under sides.

ARICIA. A genus of Dorsibranchiate Annelids. They have neither teeth nor tentacles. The body, which is lengthened, bears two ranges of lamelliform cirrhi along the back; and the anterior feet are furnished with denticulated crests, that do not occur on the other feet.

ARMADILLO. (*Dasypus*.) A genus of mammiferous quadrupeds, belonging to the order *Edentata*, readily distinguished from all others by the singular covering with which Nature has protected them. This is a complete suit of armour; consisting of a triangular or oval plate on the top of the head, a large buckler over the shoulders, and a simi-

lar buckler over the haunches, while between these solid portions there intervenes a series of transverse bands or shelly zones, in such a manner as to accommodate this coat of mail to the various postures of the body; the tail also is covered by a series of calcareous rings; and the animal altogether exhibits a striking deviation from the usual structure and outward appearance of quadrupeds. Like the hedgehog, it can roll itself up into a ball, thereby offering a uniform, solid surface, impervious to the attacks of birds of prey or small quadrupeds. The interior surface of

SMALL ARMADILLO.
(*DASYPUS HEXODONTUS* VAR.)

the body, not covered by the shell, is clothed with coarse, scattered hairs, of which some are also seen to issue forth between the joints of the armour. The Armadillos have a rather pointed snout, long ears, short and thick limbs, and stout claws; all of which are adapted to their habits of burrowing, which they perform with such astonishing rapidity that it is almost impossible to get at them by digging. The hunters are then obliged to strike them out of their dens; and as soon as they reach the surface they roll themselves up, and are easily captured. Although they abound in incredible numbers, were it not for their peculiar fecundity they would be speedily exterminated, as they are sought with great avidity on account of their flesh, which is roasted in the shell, and is regarded as a great luxury. Their food consists chiefly of succulent roots, ripe fruits, and other soft vegetable substances; but they also greedily devour worms, small lizards, ants, and the eggs of birds which build their nests on the ground. The species are distinguished from each other, principally, by the number of bands on the trunk of the body, between the shield on the fore-shoulders and that on the rump. Don F. Azara, however, in his "Essays on the Natural History of the Quadrupeds of Paraguay," showed that the number of these bands is by no means constant in the same species, but that within certain prescribed limits this number varies according to the age and sex of the individual. Baron Cuvier, accordingly, for greater facility of definition, has divided the whole genus into five small groups, principally distinguished from one another by the number and form of their teeth and claws; and to these sub-divisions he has applied, re-

spectively, the names of *Cachicameas*, *Apars*, *Encouberts*, *Cabassons*, and *Priodontes*.

The *CACHICAMEAS* are those which have four toes on each foot, and seven teeth on each side in both the upper and lower jaws. —The *APARS* have also four toes on each foot, and nine or ten teeth on each side above and below. The *Apar* has only three moveable bands; the rest of its tessellated covering being nearly inflexible: it has also the power of rolling itself into a perfect sphere, in which state it is safe from the attack of dogs; its smooth hard covering offering a better defence than the sharp spines of the hedgehog. —The *ENCOURBERTS* have five toes on the fore-feet, and in addition to nine or ten teeth on each side in both jaws, have two incisor teeth in the upper. —The *CABASSONS* have five toes; but those of the fore-feet are obliquely placed, so that the thumb and index finger are small, but the middle and fourth claws are armed with immensely large trenchant claws; on each side above and below are nine or ten teeth. —The *PRIODONTES*, in addition to the unequal toes and enormous claws of the *Cabassons*, have, on each side of both jaws, twenty-two or twenty-four small teeth. The *GIANT ARMADILLO* (*Dasypus gigas*) belongs to this division.

GIANT ARMADILLO.—(*DASYPUS GIGAS*.)

It is the largest known species of Armadillo; the body, exclusive of the tail, being sometimes three feet in length.

The *PICHY* (*Dasypus minutus*), as we read in Mr. Darwin's "Researches" in South America, wanders by day over the open plains, feeding on beetles, larvae, roots, and even small snakes. It prefers a very dry soil; and the sand-dunes near the coast, where for many months it can never taste water, is its favourite resort. The instant one was perceived, it was necessary in order to catch it, almost to tumble off one's horse; for if the soil was soft, the animal burrowed so quickly, that its hinder quarters had almost disappeared before one could alight. The *Pichy* likewise often tries to escape notice by squatting close to the ground.

It is an interesting fact, fully proved by the remains of extinct species discovered by the above-named traveller, that more than one gigantic animal, protected by an armadillo-like covering, were once inhabitants of this earth, but at a period so remote as to render all attempts to ascertain their exact nature perfectly unavailing: much, however,

has been done towards it by the aid of modern science. [See TOXODON and GLYPTODON.]

ARNEE. (*Dos Arni*.) A large and formidable quadruped, conspicuous for courage, strength, and ferocity; and closely allied to the wild ordinary Buffalo. It inhabits the high lands of Hindostan, and is remarkable for its enormous horns, which often measure from four to six feet in length. They incline outwards and backwards, and then, arching gradually towards each other as they proceed to the points, form a bold crescent: they are rough with numerous ridges and furrows. In Bengal and the neighbouring provinces this animal is known by the name of *Arna*.

ARTAMUS. A genus of birds, one of the species of which was placed by the older writers among the Shrikes. [See WOOD-SWALLOW.]

ARTICULATA. The term applied by Cuvier to a primary division of the animal kingdom. The animals composing it not only present an internal structure which is essentially different from that of the other three divisions—the VERTEBRATA, MOLLUSCA, and RADIATA—but are distinguished by external characters so definite and evident as not to be mistaken. The skeleton is not internal, as in the Vertebrata, but is seldom altogether absent, as in the Mollusca. Their entire body is divided into segments; the series of articulated rings which encircle the body supplying the place of a skeleton, and being in general hard enough to furnish the necessary resisting fulcrum to the muscles of locomotion; whence they are capable of performing the several actions of walking, leaping, swimming, or flying. There are also some which are not furnished with feet, but have only soft and membranous articulated limbs, by which they can merely crawl. In some articulated animals, their ring-like appearance results merely from a certain number of transverse folds, which furrow the skin, and encircle the body; but in the greater number, the animal is enclosed in a kind of case, formed by a series of rings, so united one to another as to allow them in certain degree of movement. In most animals of this sub-kingdom, each ring in its complete state possesses a pair of nervous ganglia, united on the central line; and these ganglia are connected together by a double cord of communication, which runs along the ventral or lower surface of the body. The bulk of the body in the Articulate is made up of the muscles, by which the several segments, and their various appendages, are put in motion; and these muscles are arranged with so much regularity and exactness on the two sides of the central line, that the lateral symmetry of the Articulate is most exact. With the exception of a few of the very lowest species, all the Articulate are furnished with a distinct head, and with jaws for the prehension and reduction of the food; these jaws, however, do not open vertically, as in the Vertebrata, but laterally, and there are frequently several pairs of them, one behind the other. All the actions of the Articulate are performed with great energy; and at the time of the

most rapid increase of the body, the demand for food is so great, that a short suspension of the supply proves fatal.

The members of this great division are distributed into five classes, principally founded on the organs of locomotion. 1. The ANNULINÆ, or *Red-blooded Worms*; characterized by the presence of a distinct circulating system, and of respiratory organs; the extension of the body into numerous segments; and by the possession of a well-developed nervous system. 2. The CHIRIPEDES, which seem, as it were, to connect the Articulate with the Mollusca. The body is furnished with articulated cirri, arranged in pairs, while in many it is provided with a multivalve shell. 3. CRUSTACEA, or *Crabs, Lobsters, &c.* These have articulated limbs, more or less complicated, attached to the sides of the body. Their blood is white, their respiration aquatic, and among them alone, of all the Articulate, do we find a distinct auditory apparatus. They have transverse jaws; two compound eyes; and all are furnished with antennæ or articulated filaments attached to the head, of which there are generally four. 4. ARACHNIDA, or *Spiders, Mites, &c.* In common with a great number of the Crustacea, these have the head and thorax joined into a single piece with articulated limbs on each side; their mouth is armed with jaws, but they have no antennæ. 5. INSECTS; the most numerous in species of any throughout the Animal Kingdom. They are characterized by the division of the body into three distinct portions,—the head, thorax or coxosteel, and abdomen; by the possession of antennæ on the head; of three pairs of legs, and, in general, of one or two pairs of wings; and by their respiring by means of *tracheæ*, which are elastic vessels that receive the air by orifices termed *stigmata*, pierced in their sides, and which are distributed by minute ramifications over every part of the body.

ARVICOLA. A genus of Rodent Mammalia. [See VOLE.]

ASCARIDÆ. A family of Entozoa, living in the alimentary canal or intestines of various animals. Their bodies are elongated, like the garden worm, round, elastic, and tapering at either extremity. The mouth is provided with three lips or tubercles; but there are no bristles or setæ on the surface of the skin, and they also differ from the earth-worm in having colourless blood, and in exhibiting very slight movements during life. The species are very numerous and common, those most familiar to us being the *Ascaris lumbricoidea*, infesting man; the *A. marginata*, found in the pig; the *A. mystax*, constantly present in the stomach of the Cat; and the *A. suilla* of the Hog or Sow. The Ascaris occupying our bodies frequently gives rise to disagreeable symptoms, and uneducated people sometimes describe these creatures to be serpents, eels, &c., having no knowledge of their true nature. The *A. lumbricoidea* varies from four to fourteen inches in length, and from one to four lines in circumference. The body is marked by numerous closely set rings or annulations,

and from head to tail by four equidistant longitudinal lines. The worm presents a light yellow colour, the skin itself being transparent and horny (chitinous) in texture. The digestive tube exhibits different degrees of width at those parts of the canal respectively known as the œsophagus, stomach, and intestine, the latter being straight in the main, but slightly undulating; the anus forms a transverse slit near the extremity of the body. This animal is unisexual, the females being furnished with oval-shaped eggs, which, according to the calculations of Eschricht, amount to many thousands in each individual. Of late years numerous experiments have been made with the view of ascertaining how these creatures gain access to the human body; and from the researches of Küchenmeister, Verloren, Leuckart, Richter, and other distinguished helminthologists, it would appear that we must in the first instance unconsciously swallow the minute eggs which exist in all open waters, and into which the eggs themselves must have been introduced in ways too numerous and unpleasant to be minutely particularised in this place. The young worms develop into active embryos whilst the ova are still in the water, but upon being transferred to the human stomach, it is conjectured that they immediately effect their escape from the shell, attaining maturity in the body of the individual (or host, as the Germans call him) who is unluckily destined to entertain their presence.

The Little Maw or Thread-worm of children will be found described under *Oxyurus*. [See SUPPLEMENT.]

ASCIDIA. An order of Acephalous Mollusks answering to the Tunicata of most zoologists. The simple Ascidians have the body fixed, roundish, and apparently issuing from a sheath. There are many species, most of which are inhabitants of the European seas, in high latitudes. They adhere by their base to rocks, shells, and other submarine substances; they are more or less gelatinous, and some are esculent; they contract and dilate themselves alternately, and have the power of squirting out the water they have imbibed. This power of ejecting the contents of the branchial sac is, in fact, their principal means of defence: some of the larger species are able to shoot the fluid to a height of three feet. Some of the Ascidians are compound; different individuals being united together by a common stem; but each having its own heart, respiratory apparatus, and digestive system; and each fixed on a footstalk that branches from a common creeping stem, through which a circulation takes place that connects them all. Both in the solitary and compound Ascidians, the young animal, when it first issues from the egg, has active powers of locomotion, being provided with a large tadpole-like tail, by the aid of which it is propelled through the water. [See SALPA, PYROSOMA, PHALLUSIA, in SUPPLEMENT.]

ASILUS: ASILIDÆ. A genus and family of Dipterous insects; the most com-

mon European species of which is the *Asilus crabroniformis*, an insect nearly equalling a hornet in length, but of a much more slender and pointed form; and, though of a somewhat formidable aspect, incapable of piercing with any degree of severity.

ASP. (*Cobulus aspis*.) A species of venomous Serpent, often mentioned both by Greek and Roman writers (who, from the discrepancies in their accounts of it, appear to have known several noxious reptiles under this name); but most especially celebrated as the instrument chosen by Cleopatra to put an end to her existence after the defeat of Mark Antony at the battle of Actium. Naturalists now concur in the opinion that the real Asp is the serpent to which the Arabs give the name of *El Haje*; that it is of a green colour, marked obliquely with brown bands, and measures from three to five feet in length. Like the Cobra Capello of India, the Asp has the power of greatly distending the neck when irritated, and of raising itself on its tail to dart forward upon an enemy. The effects of its poison are most deadly, admitting of no remedy where amputation of the part cannot be immediately effected; but Lord Bacon asserts that its bite is the least painful of all the instruments of death, and he supposes its poison to have some affinity to opium, though less disagreeable in its operation.

ASPERGILLUM. A genus of Molluscous animals, furnished with a bivalve shell, inclosed in a tubular calcareous sheath, which is dilated or club-shaped at the lower end, and gradually lessens in diameter to the narrow aperture. The shell, which derives its name from its resemblance to the spout of a watering-pot (a name familiarly given to it by collectors), has the form of an elongated cone, terminating at the large end in a disc, which is pierced with a number of small orifices, and bordered by a sort of corolla or frill. By means of two small valves in the tube the water is freely admitted into the interior of the shell. The animals of this genus are borers; some bury themselves in the sand, some in stone, others in wood, and others in thick shells.

ASPIDIPHORA. The name given to a group of Branchiopodous Crustacea, distinguished by having sixty pairs of legs, all furnished on the outside, near the base, with a large oval vesicle, and of which the two anterior, much larger than the rest, resemble antennæ. A large shell, almost entirely disengaged, covers the major part of the upper side of the body. [See BRANCHIOPODA.]

ASS. (*Equus asinus*.) A well-known and most useful domestic quadruped, whose good qualities are too generally undervalued. The Ass is believed to be a descendant of the wild *Ass*, inhabiting the mountainous deserts of Tartary, &c. (by some naturalists called the *Osaor*, and supposed to be identical with the Persian *Koulan*), and celebrated in sacred and profane history, for the fiery activity of its disposition, and the fleetness of its course. But

in the state of degradation to which for so many ages successive generations have been doomed, the Ass has long since become proverbial for stolid indifference to suffering and for unconquerable obstinacy and stupidity.

From the general resemblance between the Ass and the Horse, it might naturally enough be supposed that they were very closely allied, and that one had degenerated: they are, however, perfectly distinct; there is that inseparable line drawn, that barrier between them, which Nature provides for the perfection and preservation of her productions—their mutual offspring, the mule, being incapable of reproducing its kind.—The best breed of Asses is that originally derived from the hot and dry regions of Asia; at present, perhaps, the best breed in Europe is the Spanish; and very valuable Asses are still to be had in the southern portion of the American continent, where during the existence of the Spanish dominion the breed was very carefully attended to. In truth, wherever proper attention has been paid to improve the breed by crossing the finest specimens, he is rendered nearly if not quite equal to the horse for most purposes of labour; while on hilly and precipitous roads he is decidedly better adapted from his general habits and formation. The most general colour of the Ass is a mouse-coloured grey, with a black or blackish stripe, extending along the spine to the tail, and crossed by a similar stripe over the shoulders.

The female goes with young eleven months, and seldom produces more than one foal at a time: the teeth follow the same order of appearance and renewal as those of the horse. Asses' milk has long been celebrated for its sanative qualities: invalids suffering from debility of the digestive and assimilative functions make use of it with great advantage; and to those also who are consumptive it is very generally recommended.

THE WILD ASS (*Equus hemionus*). [or KOULAN, as it is called by the Persians] stands much higher on its limbs than the

WILD ASS.—(*EQUUS HEMIONUS*.)

common Ass; its legs are more slender, the forehead is more arched, and it is altogether more symmetrical. The mane is composed of a soft woolly dusky hair, about three or four inches long; the colour of the body is a fine silvery grey; the upper part of the face, the sides of the neck and body, being of a

flaxen hue; and a broad brown stripe running down the back, from the mane to the tail, and crossing the shoulders, as in the common Ass. The Koulan inhabits parts of Central Asia, and migrates from north to south, according to the season. Its flesh is held in high esteem by the Tartars and Persians, who hunt it in preference to all kinds of game. We have alluded to the frequent mention of this animal by both sacred and profane writers of antiquity; and we may properly conclude by quoting the book of Job, xxxix. 5-8: "Who hath sent out the wild ass free? or who hath loosed the bands of the wild ass? Whose house I have made the wilderness, and the barren land his dwellings. He scorneth the multitude of the city, neither regardeth he the crying of the driver. The range of the mountains is his pasture, and he searcheth after every green thing." [See KIANO in SUPPLEMENT.]

ASSERADOR. (The Spanish word for *Sawyer*.) The name applied in Columbia to a remarkable Lamellicorn beetle, which will be better understood by the accompanying wood-cut than by any description. The

HEWITSON'S BEETLE.
(ASSERADOR HEWITSONI.)

female wants the singular horns on the head and thorax from which the species derives its local name of "The Sawyer;" it being the belief of the country people that the insect saws off the small twigs of trees by means of the friction of the two. Mr. David Dyson informed us that he found it abundantly, and in clusters, on a species of bamboo. Mr. Empson of Bath first discovered this curious insect, and published a figure of it with the name of *Asserador Hewitsoni*, and presented his unique specimen to the British Museum at a time when the insect was very rare. It has also been described by Mr. Hope as the *Golafa Porteri*, and by Erichson as the *Scarabeus Petiverii*; and we see the learned Berlin entomologist now fancies it may be only a variety of the Fabrician species, *S. ageon*. We give this one example of what naturalists call the *synonymes* of a species, to show the utter impossibility of our attempting to give or to reconcile the different names applied to the same species by different authors.

ASTACUS. A genus of long-tailed Crustaceous animals, whose distinguishing cha-

nacter is derived from the antennæ, the two pairs of which are inserted in the same horizontal line. In it are included those well-known and valuable shell-fish, the Lobster (*Asacus murinus*), and the Crayfish (*Asacus fluviatilis*): the former of these has, however, by recent naturalists been regarded as the type of another genus (*Homarus*). [See LOBSTER and CRAYFISH.]

ASTERIAS. A genus of Radiated animals, of a more or less stellate form, which

STAR-FISH—(ASTERIAS.)

we find thrown up on every coast, and which are popularly known as *Star-fishes*. They are formed of a semi-transparent and gelatinous substance covered with a thin membrane; and though at first sight they often appear like a lump of inanimate tissue, on minutest inspection they are found possessed of life and motion. "Let a star-fish thus picked up," observes Mr. Rymer Jones, "be placed in some transparent pool left by the tide, within a rocky basin; watch it there, and, doubtless, soon the most inquisitive looker-on will find himself compelled to gaze in mute astonishment at what he sees. From the inferior surface of each ray, the creature, which before appeared so helpless and inanimate, slowly protrudes numbers of fleshy tubes, which move about in search of firm holding-places, and are soon fixed, by means of little suckers at the end of each, to the smooth surface of a neighbouring stone, or, if the star-fish has been placed in glass filled with salt water, to the inner surface of the glass, where every movement may be plainly seen. When these have laid fast hold, others appear in quick succession, and likewise are attached to the smooth surface, till at last hundreds of little legs, for such these suckers seem, are actively employed, and by their aid the creature glides along with such a gentle motion, that it seems rather to swim than crawl. Thus roused into activity we watch its movements, and perceive that it has appetites and instincts which direct its course. Place within its reach a piece of tainted fish, or other sea-side carrion, and it soon will find it out, and, clasping it between its rays, will swallow and digest it in its ample stomach."

ASTERACANTHION. [See SUPPL.]

ASTEROLEPIS. [See SUPPLEMENT.]

ASTRÆA. A genus of fixed Polypi, either incrusting marine bodies, as in the *Astræa rotulosa*, an inhabitant of the West Indian seas, or collected in a hemispherical mass, sometimes though rarely lobated, as in the *Astræa savosa*, commonly found in the seas of the East Indies.

ATELES. [See SPIDER-MONKEY.]

ATHERICERA. The fourth section of Dipterous insects, characterised by the an-

tennæ being only two or three-jointed, and the proboscis capable of being withdrawn into the mouth. Few of the Athericerae are carnivorous in the perfect state. They are found, for the most part, on flowers leaves, and sometimes on human excrement.

ATHERINE. (*Atherina*.) A genus of Acanthopterygious fish, of which there are several species, varying in length from three inches to six. They are abundant on the shores of Italy and Greece, as also on the Peruvian and other coasts of South America, where they are esteemed delicious food. They are likewise taken in considerable numbers on the south-western coasts of England, especially near Southampton, where, from their similarity of appearance, they are called *smelts*. The Atherine is of a silvery yellow hue, somewhat transparent, and having a well-defined silvery band or stripe running along the sides, from gills to tail.

ATLANTA. (*Atlanta Peronii*.) A small transparent Molluscous animal, found in the seas of all hot climates; it occupies a most delicate shell spirally rolled on itself, having a thin and glassy operculum. The Atlanta belongs to the order *Heteropoda*: it has two tentacula, with large eyes at the base; and the foot large.

ATTAGEN. A local name for the Flamingo or White Grouse. [See PTARMIGAN.]

ATTIHAWMEG. [See SALMO ALBUS.]

AUK. (*Alca*.) A genus of aquatic birds of the family *Alcedæ*, consisting of several species; particularly the Great Auk, the Razor-bill, and the Little Auk. They are characterized by having very short wings, and the legs placed so far behind the centre of the body that they stand nearly erect. They are strictly sea birds, and nestle on its borders; breeding in caverns and rocky cliffs, and laying only one large egg. They obtain their food by diving, at which they are very expert; but the power of their wings is very limited; and when they proceed on foot by land, which they do with swiftness, if pursued, their motions are the most awkward ungainable. They all feed on small fishes, crustacean, vermes, mollusca, or marine vegetables.

The GREAT AUK (*Alca impennis*) is three feet long; and has a black bill, four inches

GREAT AUK.—(ALCA IMPENNIS.)

and a quarter long, both mandibles being crossed obliquely with several ridges and furrows. Two oval-shaped white spots occupy nearly the whole space between the bill and the eyes: the head, back part of the neck, and all the upper parts of the body and wings are covered with short, soft, glossy black feathers, excepting a white mark across the wings, formed by the tips of the lesser quills. The wings do not exceed more than four inches and a quarter from the tips of the longest quill-feathers to the first joint: legs black, short, and placed near the vent. This species inhabits Norway, Iceland, Greenland, and the Feroe Islands. They are, sometimes, though very rarely, met with on the northern isles of Britain, but are never observed to be at any great distance from the shore. A British-killed specimen is in the British Museum; it was formerly in the collection of Mr. Bullock.

The **RAZOR-BILL**, or Common Auk, (*Alca torda*). These birds abound in the higher northern latitudes; they are, however, widely diffused; and in England many precipitous cliffs, the Needles, &c., have a fair share of them. The Razor-bill is about eighteen inches long, and the extended wings about twenty-seven inches. They build no nests, but lay their eggs upon the bare edges of lofty rocks hanging over the sea, where they form a very grotesque appearance, from the singular order of the rows in which they sit one above another. Their [one] egg is disproportionately large, being three inches long, the colour a greenish-white irregularly marked with dark spots. Thousands of these birds are killed on the coast of Labrador, for the sake of the breast feathers, which are very warm and elastic; and incredible numbers of eggs are also collected there.

The **LITTLE AUK** (*Merculus alle*). This is a plump round-shaped little bird, about nine inches long. The crown of the head is

LITTLE AUK. — (MERGULUS ALLE.)

flat and black; nearly all the upper parts of the plumage are of the same colour; the cheeks and under parts white; legs and toes yellowish. These birds inhabit the inhospitable shores of Greenland and Spitzbergen; but their great breeding station is said to be in the northern part of Baffin's Bay. In these dreary regions, we are told, when the

ice has been broken up by storms, they watch its motion, and come down in legions to banquet on the various marine animals which lie scattered before them. It is rarely that the Little Auk is seen on our shores, and can hardly be called an occasional visitant. Like the others which have been mentioned, it only lays one egg, which is of a pale bluish-green, and is placed on the most inaccessible ledges of rocks.

Different species of this family of birds are spread over various parts of the northern world; and some of them are met with on almost all the rocky cliffs on the coasts of Britain and Ireland. The female deposits her single egg upon the bare mould, in a hole dug out and formed in the ground by herself and mate, for that purpose, or in one that they find ready made by the rabbits, which they easily dislodge. They assemble early in April, prepare for the business of incubation in May, and hatch their young in the beginning of July; from which time till the middle of August they are employed in nurturing and rearing their brood; they then regularly depart for the southern coasts of France, Spain, and other regions more suited to their exigencies, where they pass the remainder of the year.

AULOSTOMA. A genus of Acanthopterygian fishes, closely allied to *Fistularia*, from which they are distinguished by having

TRUMPET-FISH. — (AULOSTOMA CHINENSIS.)

numerous free spines before the dorsal fin: the jaws are toothless; the tube of the muzzle is shorter, wider, and more compressed than in *Fistularia*; the body is very scaly; the tail is short and slender, ending in a common fin: the air-bladder is also larger than in the true Pipe-fishes. The best known species is a native of the Eastern seas.

AURICULA. A genus of Molluscous animals, having a head furnished with two tentacula, and eyes at their base; foot short and narrow. They inhabit a shell having a fancied resemblance to the ears of certain

MIDAS' EAR. — (AURICULA MIDEA.)

animals; hence the name. Several species are European; others are found on the banks of rivers in Brazil, and the Indian and American islands. The species known as

Auricula Mula, or *Midas' Ear*, is a handsome shell, native of the East Indies: its figure is oval or oblong; the mouth longitudinal, with a reflected lip.

AUXIS. A fish belonging to the *Scomberidae* or Mackerel family, found in the Mediterranean. It is of a fine blue black on the back, with oblique blackish lines, and the flesh deep red.

AVES. [Birds.] The name of a class of vertebrated animals, characterized by oviparous generation, a covering of feathers, and by their anterior extremities being organized as wings, and mostly used for flight. There are six orders, which are distinguished by certain characteristics of the posterior extremities or feet. The **FIRST** order is termed *Raptores* or *Accipitres*; they have large feet, with three toes before and one behind, all armed with long, strong, sharp, curved, and prehensile talons; this structure is associated with a strong, curved, and sharp-pointed beak; a very muscular body; and capability of rapid and long-continued flight. These are Birds of Prey; the principal of them being Vultures, Eagles, Hawks, Kites, Buzzards, and Owls. The **SECOND** order is termed *Insectores*, or Perching Birds. The feet of these are all formed for perching, and their power of grasping is very great; the toes are slender, flexible, of moderate length, and provided with long, pointed, and slightly curved claws. It includes the Thrushes, Nightingales, and all the sweetest songsters of our groves; with the Redbreasts, the Sparrows, Larks, Swallows, Crows, Kingfishers, Birds of Paradise, and Humming-birds. From including the smaller tribes of Birds, the term *Passeres* is also given to this order.

The **THIRD** order is termed *Scansores*, or Climbers. These have the power of throwing one of the fore toes back at pleasure; a construction which enables them to climb the perpendicular trunks of a tree. Of this order the Parrot tribe and the Woodpeckers are the principal members. The **FOURTH** order is termed *Rasores*, or Gallinaceous Birds. It is characterized by the hinder toe being raised above the level of the three anterior ones; this reduces the power of perching; but the front toes are united by a slight membrane, and are strong, straight, and terminated by robust, obtuse claws, adapted for scratching up the soil, and for running along the ground; for which purpose they are also furnished with very strong, muscular legs. These birds have the head small in proportion to the body; and the bill generally short, with the upper mandible somewhat curved. In this order are comprised the Peacock, the Turkey, the common Cock and Hen, Partridges, Pheasants, Pigeons, &c. The **FIFTH** order is termed *Grallatores*, or Waders. To enable them to wade and seek their food in water, along the margins of rivers, lakes, and estuaries, the birds belonging to this order have long and slender legs, and generally bare thighs. Their three front toes are more or less united at the base by a web, and the central toe is often longer and stronger than the rest; the hind toe is elevated, short, or even sometimes wanting.

This order comprises the Ostriches, Cranes, Herons, Storks, Snipes, Woodcocks, Bustards, and Plovers. The **SIXTH** order is termed *Natatores*, *Palmipedes*, or web-footed Birds; and their whole organization is especially adapted for an aquatic life. Their legs are short, and placed behind the centre of equilibrium; their fore toes are united by a thick and strong web or membrane; and their bodies are covered with a dense layer of down, beneath the outer plumage, which is close, and rendered impervious to the water. The order comprises Swans, Ducks, and Geese; Auks, Penguins, Pelicans, Petrels, Coots, and Grebes. [See the art. BIRDS.]

AVICULA. A genus of Conchiferous Molluscs belonging to the order *Diphyaria*. It is thus defined by Cuvier:—"The shell has the valves equal, with a recilinear hinge, and is often carried out into wings; the ligament is narrow and elongated; small dentulations often appear on the hinge, on its anterior part; and below the angle on the side near the mouth is the notch for the *byssus*. The anterior abductor muscle is still extremely minute." The foot of the animal is conical, worm-shaped, and rather long. Some very beautiful species of the *Avicula* are brought from the Indian Ocean, coast of Brazil, New Holland, the Red Sea, &c. The interior of the shell is pearly in the centre: some species have a broad black border surrounding it, and the margin terminating in a fringe. The *Avicula nargatifer*, or Pearl Oyster, belongs to this genus. [See PEARL OYSTER.]

AVICULARIA. [See SUPPLEMENT.]

AVOSET. (*Recurvirostra avocetta*.) This gallinaceous bird, whose great singularity is in the form of its bill, is aquatic, the shores of the ocean and the banks of estuaries being its favourite haunts. On the shores of the Caspian and the salt lakes of Tartary they are abundant; they are widely distributed through the temperate climates of Europe; and on the south-eastern coast of England they are occasionally found. The Avoset is about eighteen inches in length; very erect, and has legs unusually long for its size.

AVOSET -- (RECURVIROSTRA AVOCETTA.)

The bill, which is three inches and a half in length, turns up like a hook, in an opposite direction to that of the hawk or parrot, and is flat, thin, sharp, and flexible. The plumage is black and white, tail con-

they throw and roll down stones, to resent the injury.

THE COMMON BABOON. (*Cynocephalus papio*.) This species is a native of the coast of Guinea, and is the one most commonly exhibited by itinerant showmen. Its appearance is at once grotesque and formidable; its nervous limbs and compressed form indicate great force and agility; the anterior parts especially being extremely strong and muscular. It is of a uniform yellowish-brown colour, with a shade of light red upon the head, shoulders, and extremities; the face, ears, and hands naked, and entirely black. The cheeks are considerably swollen below the eyes; after which the face contracts suddenly, which gives the nose the appearance of having been broken by a violent blow. It is furnished with whiskers, which have a backward direction, but do not conceal the ears. While young, this Baboon is gentle and familiar; but as it approaches adult age, it displays all the repulsive manner, the ferocity and intractability common to the rest of its kind.

THE MANDRILL, or VARIEGATED BABOON. (*Cynocephalus maimon*.) The Mandrill is the most remarkable of the whole genus for brilliancy and variety of colour, while for size it is unequalled by any other Baboon, its height when standing upright being upwards of five feet. The limbs

MANDRILL. — (*CYNOCEPHALUS MAIMON*.)

are large and muscular, the body thick and robust; the head large, face long, scarcely any forehead, and the snout ending abruptly; the eyes small and deeply sunk in the head; the cheek-bones enormously swollen, and marked with several deep furrows of violet-blue, purple, and scarlet; and the muzzle and lips large and protuberant. The hair of the forehead and temples rises, in a remarkable manner, into a pointed form, which gives the head a triangular appearance; and a small pointed orange-yellow beard adorns the chin. Round the back of the neck the hair is long, and inclines forward, somewhat in the manner of a wreath. On the loins the skin is almost bare and of a violet-blue colour, gradually altering into a bright blood-red, which is more conspicuous on the hinder parts, where it surrounds the tail, which is very short, and generally carried erect. In most of its habits the Mandrill resembles the other Baboons, especially in its growing more morose as it advances in age, and in becoming offensively illudinous. In their wild state they generally march in

large bands, and are so formidable that not only are the inhabitants afraid to meet them in the woods, unless they are in considerable companies and well armed, but the beasts of the forest, including even the elephant, quit their respective haunts at the approach of the powerful and savage animals whose habits we have endeavoured to describe. To this truly formidable species belonged "Happy Jerry," long kept in the fine menagerie of Mr. Cross. He was trained to smoke a pipe, and seemed to relish a pot of porter; but he was fierce to most persons who approached him, unless they were his keepers. His stuffed skin and skull may now be seen in the magnificent collection of the British Museum.

There are several other species which our limits forbid us to do more than merely mention; as, the DRILL, the WOOD-BABOON, the PIOTAIL, the CRESTED, the YELLOW, the CINEREOUS, and others.

BABYROUSSA. (*Sus Babirussa*.) This animal is nearly of the size of a common Hog, and has generally been referred to the Hog genus, though in many respects it is essentially different; its form being longer, its limbs more slender, and, instead of bristles, being covered with fine, short, and somewhat woolly hair, of a dark brown colour, interspersed with a few bristles on the upper and hinder part of the back. It is still further distinguished by the very extraordinary position and form of its enormous upper tusks, which, instead of being situated internally, on the edge of the jaw, as in other animals, are placed externally, perforating the upper lip, and turning upwards toward the forehead, like the horns of the Kumiandtia: the tusks of the lower jaw are also very long, sharp, and curved; but not of equal magnitude with those of the upper. The tusks are of a very fine ivory, but neither so hard nor so durable as that of the elephant: the eyes are small; the ears erect and pointed; the tail rather long, slender, and tufted at the end with long hairs.

BABYROUSSA. — (*SUS BABIROUSSA*.)

The Babyroussa is a gregarious animal, inhabiting the woods of Java, Amboyna, the Celebes, and other Indian islands, where large herds are met with. Their food consists chiefly of vegetables, and the leaves of trees. When sleeping or resting themselves in a standing posture, they are said often to hook or support themselves by placing the

upper tusks across the lower branches of the trees, and, thus suspended, sleep in security. When hunted closely, and in apparent danger, this animal will, if possible, plunge into some great river, or the sea, where it swims with great facility, and by alternate diving and rising, is frequently able to escape from its pursuers. In the gardens of the Zoological Society a fine specimen of this rare animal may now be seen.

BACULITES. A species of Ammonite or Snake-stone. [See AMMONITE.]

BADGER. (*Meles vulgaris*.) The Badger is a carnivorous quadruped inhabiting most parts of Europe and Asia; and is generally regarded as a solitary, stupid animal, that seeks refuge in the most sequestered places,

BADGER. — (MELES VULGARIS.)

and shuns the light of day. It has very short legs and a broad flat body; the head is long and pointed, the eyes small, the neck short and thick, the tail remarkably short, and the hide thick and tough. The upper parts of the body are covered with long coarse hair, the hue of which is a rusty grey; but on the breast, belly, and limbs it is short and black; the face is white, and along each side of the head runs a long pyramidal band of black, including the eyes and ears.

With its powerful claws it constructs a deep and commodious burrow; and as it continues to bury itself, it throws the earth behind it to a great distance, and thus forms for itself a long winding hole, ending in a round apartment at the bottom, which is well lined with dry grass and hay. This retreat it seldom quits till night, when it steals from its subterranean abode for the purpose of procuring food. It lives chiefly on roots, fruits, insects, and frogs; but it also robs the bee of his honey, and destroys the eggs of partridges and other birds which build their nests on the ground. It is quiet and inoffensive; but when attacked by dogs it defends itself with great resolution, and seldom dies unrevenged of his enemies. The Badger is about two feet six inches long: his skin is so thick that it resists the impression of the teeth, and so loose, that even when a dog has seized it, he is enabled to turn round easily, and severely bite his assailant. The female produces three or four young at a time. The flesh of the Badger is reckoned a delicacy in Italy, France, and China, and may be made into hams and bacon. The skin, when dressed with the hair on, is impervious to the rain, and consequently makes

excellent covers for travelling trunks, &c.; and the hairs or bristles are made into brushes for painters.

The **AMERICAN BADGER**, or **CARCAJOU**. (*Meles Labradorica*.) This animal is rather smaller than the European species; its fore-claws are longer and stronger, and the black bands on the face narrower. Its prevailing colour is a kind of mottled grey, and, with the exception of the head and extremities, which are covered with short coarse hair, it is furnished with a fine, long, silky fur. It is a slow and timid animal, takes to the first earth it meets with when pursued, and, burrowing in the sand, is soon out of the reach of danger. Whilst the ground is covered with snow the American Badger seldom ventures from his hole, but passes the severe winter months in a semi-torpid state. By some naturalists this is regarded as the type of a distinct genus (*Taxidea*).

The **INDIAN BADGER** (*Mydaus colaris*) is about twenty inches in height and two feet in length, the form of its body and limbs bearing a resemblance to the bear, while its head, eyes, and tail remind us of the hog. The hair is a yellowish white, with black points, which gives the whole a dark brown shade; but the legs and under parts of the body are black. The ears are very small; and on each side of the head are two black bands, which descend down the neck, and enclose the throat. They are exceedingly fierce.

BALÆNA. [See WHALE.]

BALÆNICETS. [See SUPPLEMENT.]

BALÆNODON. A genus of extinct whales. [See SUPPLEMENT.]

BALANCE-FISH. (*Zygæna*.) A fish, the shape of whose head has been likened to a hammer. It is a native of the Mediterranean Sea. [See ZYGÆNA.]

BALANINUS. A genus of the *Curculionidae*, furnished with a long slender rostrum, or snout, at the tip of which is a minute pair of sharp horizontal jaws, and by means of which it is enabled to deposit its eggs, which are generally placed in the kernel of some fruit. Of this kind is the *Bala-*

NUT WEEVIL. — (BALANINUS NUCUM.)

ninus Nucum, or Nut-Weevil, whose larva is so commonly found in nuts, filberts, &c. The egg is introduced when the nut is young and soft; and the nut being but slightly injured, continues to grow and ripen, while the larva feeds upon the kernel in which it is imbedded. When about to change its state, it bores through the shell and escapes, leaving a small round orifice: falling on the ground, it then burrows into the earth, where it assumes the pupa state, and in the following summer it comes forth as a perfect insect.

BALANUS. A genus of multivalve Cirripedes, usually found adhering to various submarine productions, whether fixed or moveable; such as the harder sea-plants and

A GROUP OF *BALANUS OVULARIS*

BALANUS OVULARIS.

all sorts of crustaceans as well as testaceous animals, rocks, ships, timber, &c. The shell shapes itself at the base to the figure of the surface of whatever it adheres to, and from which it is with difficulty removed. It altogether forms a rude hollow cone. The animal inclosed in it is of a very singular structure: it has twelve crooked legs or arms, garlished with a great number of hairs, which it elevates on all occasions; besides eight others, inferior in size and lower in position. In general the *Balani* are considered ineligible as food: but Capt. P. P. King speaks of some large kinds (*Balanus psittacus*) on the southern parts of the South American coast as forming a very common and highly esteemed food of the natives, the flesh equalling in richness and delicacy that of the crab. He also says, it occurs in large bunches, and presents somewhat of a cactus-like appearance. The parent is covered by its progeny; so that large branches are found composed of from fifty to a hundred distinct individuals, each of which becomes in its turn the foundation of another colony.

BALD BUZZARD. [See OSPREY.]

BALEARIC CRANE. [See CRANE.]

BAITIMORE BIRD. [See ORIOLE.]

BAND-FISH. (*Cepola*.) This genus of Acanthopterygious fishes is of a form so thin and flat in proportion to its length, as to have obtained among the ancient ichthyologists the name of *Tenia* or Ribband-fish. One species (*C. Mediterranea*) is a native of the Mediterranean, and varies in length from eighteen inches to three feet. The head is short and rather truncated in front; the mouth is wide, and the lower jaw longer

than the upper, both being armed with sharp curved teeth, of which there is a double row in the lower jaw. The sides are extremely compressed; and the body, both above and below, sharpens into a kind of carina or ridge. The dorsal fin commences from the back of the head, and is continued as far as the tail; the vent fin also extends nearly throughout the whole length. The colour of the body is bright silver, with a dusky tinge above; the sides are marked with a few large reddish spots; the fins are all of a pale red colour, and the skin is covered with extremely small scales. It is predaceous, and swims with great rapidity.

Another species, found on our coasts, (*Cepola ubacensis*) is of a pale carmine colour, and varies from ten to fifteen inches in length. It is very smooth and slender, and tapers very gradually from the head to the tail.

BANDICOOT. (*Perameles*.) A genus of Marsupial animals, indigenous to Australia, and in some respects analogous to the Opossums and Kangaroos; but the disproportion between the fore and hind legs is by no means so great, though sufficient to make their gait rabbit-like, or a succession of leaps, rather than walking or running. Their feet are provided with broad powerful claws, which enable them to burrow with great facility, and to dig up roots, on which they principally feed. The most common species is called the LONG-NOSED BANDICOOT (*Perameles nasuta*): it measures about a foot and a half from the tip of the snout to the origin of the tail; the ears are erect and pointed, the eyes small, and the tail bearing considerable resemblance to that of a large overgrown rat, to which the whole animal, in fact, may be likened as regards its general external appearance, as well as its depredations upon the farm-yards and granaries.

BANXRING. [See TUTAIA.]

BARB. The name given to a fleet and vigorous breed of horses reared by the Moors of Barbary, and introduced into Spain during their dominion in that country, but since their expulsion it has been allowed greatly to degenerate; nor is it much better in their original clime, except among the wild nomadic tribes of the desert, where the breed still exists in perfection. But the Barb is far from excelling in symmetrical beauty; the true value of these noble animals is to be discovered in their qualities rather than in their appearance. With a large and clumsy head, a short thick neck, and a broad chest, are united a long body and slender legs; but, on the other hand, they are unrivalled in speed, abstinence, docility, patience, and endurance under fatigue. They are sinewy, nervous, and long-winded; they walk well, and stop short, if required, even in full career; walking and galloping, indeed, being the only paces these animals are allowed to practise. It is not customary, except in cavalry exercises, for the Moors to try the powers of their horses very severely; they then, however, gallop them at the height

of their speed. The horses are never castrated, and are alone used for the saddle, the mares being kept for breeding. It has been remarked that Barb's grow ripe, but never old, because they retain their vigour to the last; they are also said to be long-lived, and remarkably free from diseases.

BARBARY APE. (*Pithecius inuus.*) This species of Ape, which grows to the height of nearly four feet; is remarkable for docility, and, by force of discipline, is made to exhibit considerable intelligence. Its general colour is a palish olive-brown; the face is a swarthy flesh colour. It is common in Barbary and the lower parts of Africa, and is also found in considerable numbers on the rock of Gibraltar. This species was well known to the ancients, and it has been the "show-man's ape" from time immemorial. Though morose and sullen in confinement, it is represented as social, active, and courageous in its wild state, and is particularly distinguished for its attachment to its young.

BARBEL. (*Barbus vulgaris.*) A freshwater malacopterygious fish, usually frequenting the deep and still parts of rivers,

BARBEL.—(*BARBUS VULGARIS.*)

swimming with great strength and rapidity, and living not only on aquatic plants, worms, and insects, which it obtains by boring and turning up the loose soil of the banks with its snout, but occasionally by preying on smaller fishes. It is said to receive its name from the barbs or wattles attached about its mouth, by which appendages it is readily distinguished, as well as by the great extension of the upper jaw beyond the lower. It is sometimes found to weigh from fifteen to eighteen pounds, and to measure three feet in length: its more general length, however, is from twelve to eighteen inches. The general colour of the upper part of the head and body is a greenish brown; the scales are small, and in general of a pale gold colour, edged with black on the back and sides, and silvery-white on the belly; the pectoral fins are a pale brown, the ventral and anal fins are tipped with yellow; and the tail is slightly forked, and of a deep purple. The Thames produces Barbel in abundance, and of a large size. "So numerous are they about Shepperton and Walton," says Mr. Yarrell, "that one hundred and fifty pounds weight have been taken in five hours, and on one occasion it is said that two hundred and eighty pounds weight of large sized Barbel were taken in one day." The flesh of the Barbel is very coarse and unsavoury; the fish, consequently, is held in little estimation, except as affording sport for the angler.

BARBET. The Barbets are a family of birds belonging to the order Scansores, or

Climbers, and are distinguished by their large conical beak, which appears swollen, or, as it were, puffed out at the sides of its base, and by being bearded (whence the name) with five tufts of stiff bristles, directed forwards. They inhabit Java, Sumatra, &c., and sport about in all positions on the trunks and among the branches of trees, in search of insects or their larvæ, on which they feed: some of them are said also to devour small birds and fruits; the typical genera, however, appear confined to the former food. The plumage of some of the species is very brilliant.

MANY COLOURED BARBET.—(*BUCCO VARSICOLOR.*)

BARIS. A genus of Coleopterous insects, which feed upon the dead parts of trees.

BARKING BIRD. (*Pteroptochos.*) This Tenuirostral bird, which is common in Chiloe and Chonos,—islands in the South American Archipelago,—is called by the natives Guid-guid; "but its English name," says Mr. Darwin, "is well given; for I defy any one at first to feel certain that a small dog is not yelping somewhere in the forest. Just as with the Cheueau, a person will sometimes hear the bark close by, but in vain may endeavour, by watching, and with still less chance by beating the bushes, to see its author; yet at other times the Guid-guid comes fearlessly near." Its manner of feeding and its general habits are very similar to those of the Cheueau. Both species are said to build their nests close to the ground, amongst the rotten branches. [See CHEUEAU.]

BARNACLE. A name given to the cirripedes sometimes found adhering to the bottoms and sides of ships, &c. [See BALANUS.]

BASILISK. (*Basiliscus.*) The Basilisk of modern naturalists has no affinity to the malignant serpent of the poets whose very aspect the ancients believed to be fatal

BASILISK.—(*BASILISCUS MITRATUS.*)

to all who looked upon it. The animal now recognised by the name of Basilisk is a species of lizard, of a very singular shape, being distinguished by a long and broad wing-like process or expansion along the back and upper part of the tail, and furnished at certain distances with interval radii analogous to those in the wings of the *draco*, or flying lizard. This process is capable of being either dilated or contracted at the pleasure of the animal; and the occiput or hind part of the head is elevated into a very conspicuous pointed hood or hollow crest. Notwithstanding its formidable appearance, however, the Basilisk is a perfectly harmless reptile, residing principally among trees, where it feeds on insects, &c. The general colour of this animal is a pale cinereous brown, slightly varied on the back and sides with different shades of brown and blue, and silvery white on the belly. It is possessed of great activity, and from its peculiar structure can adapt itself to the watery element without inconvenience. It is most common in the tropical parts of South America.

BATS. (*Chiroptera*.) The singular animals which come under this denomination were long considered as partaking so much of the character of birds with that of quadrupeds, that it was thought difficult to assign to them a distinct station in the system of nature. Such doubts, however, have long since yielded to scientific investigation; their anatomical and intes-

BAT. — (*VESPERTILIO MURINUS*.)

tinal structure, their viviparous nature, their hair, &c., entitling them to be ranked as quadrupeds. Still it is not to be denied that their peculiar conformation is admirably calculated for the exercise of considerable powers of flight. The air, indeed, is their home: through this they move with vast rapidity, and with great apparent ease, wheeling in every direction in search of their insect prey, and performing the most abrupt evolutions to secure it. A remark, indeed, not less true than trite, has been often made that, in their mode of flight, Bats bear a very strong resemblance to swallows; exercising the same purpose in the economy of nature, in restraining the multiplication of the crepuscular and nocturnal insects, as the swallows do in regard to the diurnal.

Their senses of smell, feeling, and hearing are wonderfully acute. In many genera the nose is furnished with a membranous foliation of most delicate structure, by which

the sense of smelling is greatly refined; the ears also are in many kinds expanded and capable of being folded down; while their ample wings, and the membranous tissues of the ear and nose, are so abundantly supplied with nerves, as to enable them, even should they be deprived of sight, to pursue uninterruptedly their neral course, voiding every obstacle, and passing adroitly through the narrowest apertures.

On the approach of cold weather the Bat hibernates, and in preparing for this state of lifeless inactivity, it seems rather to select a place where it may remain safe from molestation, than where it may be commodiously lodged. "The hibernation of these animals," says Mr. Bell, "is indeed one of the most interesting points in their economy. At an earlier or later period of autumn, according to the species, they retreat, generally in large congregations of various species together, to the most retired places; as under the roofs of houses and churches, in caverns, in the hollows of trees, and similar situations, where they suspend themselves by their hinder claws, with the head downwards. Here they crowd together, holding not only by the surface of the walls of their retreat, but by each other, one crowding over another so closely that it appears scarcely possible for such numbers to occupy so small a space."

Not less than twenty species of Bats are enumerated as known in Great Britain; but these, although differing from each other, either in structure, colour, or habits, can hardly be deemed of sufficient importance to occupy the space that would be necessary to describe them minutely; we shall therefore merely refer to a few of them in the briefest manner possible, and in another place narrate a few particulars relating to two foreign species of a more formidable character.

THE COMMON BAT, or FLITTER-MOUSE. (*Vespertilio pipistrellus*.) There are several species known in England, but this is the most common. It is nearly two inches and a half long, or about the size of a mouse. The members usually called wings, are merely the four inferior toes of the forefeet extended to an enormous length, and connected by a thin membrane, reaching also to the hind legs, and from them to the tail: the body is covered with short fur, of a mouse-colour, tinged with red; and the membranes are of a deep dusky hue; the eyes are small, and the ears exactly resemble those of the mouse. This species of Bat makes its appearance in the twilight of fine summer evenings, frequenting the sides of woods, glades, and shady walks, or skimming along the surface of tranquil rivers, where moths, gnats, and other nocturnal insects are most readily to be found; but if the weather be not fine, it remains shut up in the chinks or fissures of crumbling masonry, or lies concealed in the friendly recesses of some hollow tree.

THE BARBASTELLE BAT. (*Vespertilio barbastellus*.) This species was originally described by Daubenton, in 1759, but

its first description as a native of Great Britain is due to Mr. Sowerby, who published an account of it with a figure in the *British Miscellany*. Its general colour is darker than that of any other British species, being nearly black on the back, with here and there a few white hairs, which become more numerous with age; the hinder parts are reddish brown, and the belly a pale grey. The ears, the naked part of the muzzle, and the flying membrane, are of a dusky black. Length of the head and body, two inches; extent of wings, between ten and eleven inches. The muzzle is truncated, and a groove leads on each side upwards to the nostrils. The cheeks are rather tumid, and covered with black hair, which forms a sort of moustache. The ears are about the length of the head, nearly as broad as they are long, and irregularly four-sided; the inner edges are turned back, forming a longitudinal groove just within the margin; the outer and superior angle prominent, rounded, and turned back. The eyes are very small,

BARBASTELLE BAT. — (V. BARBASTELLUS.)

placed close to the base of the auricle, and almost concealed by the hair on the cheek. The fur of the body is long and soft. Mr. Bell having had a Barbastelle Bat in his possession for some time, was able to give a few slight notices of its habits. "He fed readily on small bits of meat, and drank water. He was a timid animal, and did not evince the slightest disposition to become acquainted with me; he would take his food, however, with his companions, and was accustomed to rest with them in a cluster, at the top of the box in which they were placed. The Barbastelle certainly became torpid more readily than any of the others, and more completely so; but when awake, evinced extreme restlessness, and was incessantly biting with great violence at the wires of his box. When suffered to fly about the room, he flew very low, and less actively than any other under similar circumstances; and he was fond of lying before the fire on the hearth-rug, where he appeared quite to luxuriate in the warmth."

THE GREAT BAT. (*Vespertilio noctula*.) This was termed *altivolans* by White of Selborne, from its always flying high in the air, in pursuit of its prey. It is gregarious in its habits; the ears are short and rounded; it is about three inches long, and of a reddish ash-colour.

THE SEROTINE. (*Vespertilio serotinus*.) This species is somewhat rare in England, but very common in France. It is of a dark chestnut colour; frequents forests; is solitary in its habits; and its flight is slow.

THE MOUSE-COLOURED BAT. (*Vespertilio murinus*.) This is the largest of the British Bats, exceeding even the Noctule in its length of body and extent of wings. The head of this Bat is long, with the ears inclining backwards.

THE LONG-EARED BAT. (*Plecotus auritus*.) One of the most common of our British Bats, and at the same time one of the most pleasing in its appearance, owing to the extraordinary transparency and beauty of the ears. It is also more familiar and bold when in confinement than any other species.

THE HORSE-SHOE BAT. (*Rhinolophus*.) There is a greater and lesser variety of this animal; the former designated *Rhinolophus ferrum-equinum*, the latter *Rhinolophus hipposideros*. This genus is distinguished by a very curious nasal appendage, or foliaceous membrane at the end of the nose, shaped somewhat like a horse-shoe, and supposed to extend in an extraordinary degree the sense of smelling. The upper part of the body is of a deep ash-colour, the lower part inclining to white.

In concluding this article on Bats, we are again tempted to avail ourselves of the intelligent observations of Mr. Bell: "It is perhaps difficult to account for the prejudices which have always existed against these harmless and interesting little animals, which have not only furnished objects of superstitious dread to the ignorant, but have proved to the poet and the painter a fertile source of images of gloom and terror. That the ancient Greek and Roman poets, furnished with exaggerated accounts of the animals infesting the remote regions with which their commerce or their conquests had made them acquainted, should have caught eagerly at those marvellous stories and descriptions, and rendered them subservient to their fabulous but highly imaginative mythology, is not wonderful; and it is more than probable that some of the Indian species of Bats, with their predatory habits, their multitudinous numbers, their obscure and mysterious retreats, and the strange combination of the character of beast and bird which they were believed to possess, gave to Virgil the idea, which he has so poetically worked out, of the Harpies which fell upon the hastily spread tables of his hero and his companions, and polluted, whilst they devoured, the feast from which they had driven the affrighted guests. But that the little harmless Bats of our own climate, whose habits are at once so innocent and so amusing, and whose time of appearance and activity is that when every thing around would lead the mind to tranquillity and peace, should be forced into scenes of mystery and horror, as an almost essential feature in the picture, is an anomaly which cannot be easily explained." [See *PERORUS* and *VAMPIRE-BAT*.]

BATHYERGUS, or COAST BAT. This Rodent animal is a native of Southern Africa, frequenting sandy tracts along the coast, where it burrows with great rapidity, working out long galleries, and throwing up hil-

COAST RAT. — (*BATHYERGUS MARITIMUS*.)

locks like the mole. In some districts these are so very numerous, as to render it dangerous to pass over them on horseback, the earth where excavated often suddenly giving way. The Coast Rat is about a foot long, exclusive of the tail, which is three inches; and its general colour is greyish ash. The incisors are of an enormous size; those in the upper jaw having a longitudinal furrow down the front. The whole form and organization of this animal fit it for an underground existence; it is accordingly often called the Sand Mole.

BATRACHOIDEÆ. A family of monstrous-looking Acanthopterygious fishes, whose pectoral fins are supported upon the elongated carpal bones which in some genera perform the functions of hind feet, enabling the fish to creep over sand or mud like small quadrupeds. The ventrals are jugular, and the gill-plates and rays are enveloped in loose skin. Cutaneous appendages or barbels generally fringe the lips, or lower jaw, to the pectorals. In general the skin is destitute of scales, but is sometimes studded with bony tubercles. The skeleton is, for the most part, but imperfectly osseous. Some genera have an air-bladder, and some have not. *Batrachus* has a spiny operculum and suboperculum, and a flat head broader than the body, but not very disproportionate in length. *Lophius* has a depressed form, and *Chironectes* a compressed one, and both have monstrously large heads, with a small hole behind the pectorals for an opening to the gills. In *Malthe* the head is flat, and greatly lengthened laterally by the projection of the large subopercula. The Batrachoideæ can live long out of the water, in consequence of the smallness of their gill-openings. The *Chironectes*, in particular, are able, even in warm countries, to pass two or three days in creeping over the land. All the Batrachoideæ conceal themselves in the mud or sand, and lie in wait to take their prey by surprise. They exist in the Atlantic, Indian, and Pacific oceans; and several also inhabit the European seas.

BATRACHIANS: BATRACHIA. Frogs, Toads, and all reptiles which, like them, have soft and naked skins (i. e. uncovered with scales), and in the early stage of existence respire by means of gills.

BEAGLE. A small kind of hound, or hunting-dog, formerly much prized for its excellent scent and persevering endurance when employed in hare-hunting. It cannot indeed boast of great speed; but its "slow and sure" qualities are generally rewarded

with success, although the chase may be continued for two or three hours. There are several kinds of Beagles; as, the Southern Beagle, the fleet Northern or Cat Beagle, and a very diminutive one called the Lap-dog Beagle.

BEAR. (*Ursus*.) A well-known quadruped, belonging to a family of plantigrades, distinguished by their ponderous bulk, massive limbs, and heavy gait. There are several species of Bears. Of all the Carnivora they are the most omnivorous in their diet, — some of them living almost entirely upon vegetable food, and nearly all being capable of supporting themselves upon it: even the most carnivorous of them, however, will seldom attack man, unless provoked to do so by aggression, or strongly incited by hunger; but when attacked they prove themselves very formidable opponents. They have six incisor and two canine teeth in each jaw, twelve molars in the upper and fourteen in the lower jaw; pendactyle or five-toed feet, armed with strong claws, but which, not being retractile, are more calculated for digging and climbing than for tearing prey. For the most part Bears are unsocial animals, frequenting the recesses of mountains and caverns, and the depths of the forests. During the winter they lay up in caves and hollow trees, passing that inclement season almost without food, and in a comparatively dormant state. In Europe, Asia, and America, Bears are pretty widely diffused, but in Africa they are more rarely found. In the Alpine regions the Bear is brown; in some other parts of Europe, black; and in some parts of Norway it has been seen of a grey colour, and even perfectly white. Bears are reported to be very fond of honey, in search of which they will climb trees, in order to get at the nests of wild bees; for, notwithstanding his awkward form, the Bear is an expert climber. In Russia the skins of Bears are among the most useful as well as comfortable articles of winter apparel; and in many other northern countries they are made into beds, coverlets, caps, and gloves. In England bears' skins are used for the hammer-cloths of carriages, for pistol holsters, &c.; and the leather prepared from them is used for many purposes, as harness, &c., where strength is requisite.

The COMMON or BROWN BEAR. (*Ursus Arctos*.) This species, with some variation as to size and colour, is a native of almost all the northern parts of Europe and Asia. Its usual size is about four feet in length, by about two feet and a half in height. In its nature it is savage and solitary; and though when tamed it appears gentle and placid to its owner, it should be cautiously managed, being often capricious, treacherous, and vindictive. Its retreat, during the period of hybernation, is the natural hollow of a tree, or some cavern; but where these are not conveniently found, it will, either form a suitable den for itself by digging, or construct a rude kind of hut with branches of trees, lined with moss. Thus protected, and fat with its summer

food, it will remain without further sustenance till the ensuing spring; during which time the female generally produces two cubs, which when first born are not much larger than a mastiff's puppies.

Most writers agree that the Brown Bear was at one time common in the British islands. The Caledonian bears (another name for British with the Romans) were imported to make sport for the Roman people, to whom the excitement of witnessing the suffering of man and beast, in its most distressing shape, seems to have been but too welcome. For many years (says Mr. Broderip) it has been swept away from our islands so completely, that we find it imported for baiting, a sport in which our nobility, as well as the commonalty, of the olden time—nay, even royalty itself—delighted. A bear-bait was one of the recreations offered to Elizabeth at Kenilworth, and in the Earl of Northumberland's Household Book we read of 20*s.* for his bear-ward. In Southwark there was a regular bear-garden, that disputed popularity with the Globe and Swan theatres on the same side of the water. Now, however, so much do tastes alter (in this instance certainly for the better), such barbarous sports are banished from the metropolis."

THE AMERICAN BLACK BEAR. (*Ursus Americanus*.) This animal is somewhat smaller than the European Brown Bear just described. It has a long head, pointed nose, small eyes, and short ears rounded at the top; its limbs are strong, thick, and clumsy; its tail is short, its feet large, and the hair on the body and limbs is black, smooth, and glossy. This animal inhabits all the northern parts of America, migrating occasionally from the northern to the more southern parts in quest of food, which consists chiefly of vegetables and grain. So impetrable are their retreats during the period of gestation, that although immense numbers of Bears are killed annually in America, hardly a single female is ever found among them. The flesh of these Bears in autumn, when they are become exceedingly large by feeding on acorns and other arborescent food, is extremely delicate; the hams, in particular, are much esteemed; and the fat, which preserves a certain degree of fluidity, is remarkably white and sweet. In the *Canadian Naturalist*, by Mr. F. H. Gosse, the following account of this animal forms a portion of the author's interesting 'Conversations':—

"This species appear to be less carnivorous than the *Ursus Arctos* of northern Europe, and less ferocious. His chief food seems to be of a vegetable nature, grain, fruits, and roots. He has an appetite for pork, however, and occasionally makes a visit to the farmer's hog-sty for the purpose of cultivating an acquaintance with the grunting inhabitants. Some years ago, one of our nearest neighbours was aroused in the night by a commotion in his hog-pen; suspecting the cause, he jumped up immediately, took his gun, and saw a bear in the act of getting over the fence with a fine hog, embraced

very lovingly in his fore-paws. The man fired (while his wife held a light), and killed the intruder. It is difficult to hurt a bear with any weapon but fire-arms; he fights with his fore-paws like a cat; and so watchful is he, and so expert at warding off every blow that is made at him, that it is next to impossible to strike his head, the only part in which he is vulnerable; for you might almost as well batter a feather-bed as the body of a bear, so encased and shielded by an enormous layer of fat. In our climate he becomes torpid during winter, generally choosing for his hybernaculum some large hollow log, or a cavity beneath the root of an overthrown tree. The species is numerous in all the wooded parts of this continent, even to the shores of the Gulf of Mexico. In the southern states he commits depredations on the farmer's fields of maize: when the corn is in that milky state called 'roasting ears,' so prized for boiling and eating as a table dish, like green peas, or roasting whole on the cob, the bear manifests a singular unity of taste with the farmer, and devours and treads down a large quantity, as he finds no difficulty in climbing over the zig-zag rail fence. I have been told that he repents his nightly visit to the same field; and, what is singular, always, on such occasions, mounts the fence, night after night, at the same spot where he got over the first time. The planters take advantage of this regular habit, by fastening to the fence a heavily loaded gun at such an angle that it shall point at the bear's breast as he rises on his hind legs. The identical crossing-place is easily known by his great tracks in the soft earth. A stick is attached to the trigger, and this is made fast, at right angles, to a transverse stick resting on two forks about breast high, a few inches outside the fence. The bear rears up to put his fore-paws on the rails, and in getting over presses with his breast against the transverse stick, which drives back the trigger, and poor Bruin instantly receives the reward of his dishonesty."

THE GRISLY BEAR. (*Ursus ferox*.) The Grizzly Bear is about nine feet long, and is said to attain the weight of eight hundred pounds. The claws are long and very strong, but more adapted for digging than for

GRISLY BEAR. — (*URSUS FEROX*.)

climbing trees; the muzzle is lengthened, narrowed, and flattened; the canine teeth are highly developed, exhibiting a great increase of size and power; and the eyes are small and sunk in the head. Notwithstanding its bulky and unwieldy form, it is capable

of great rapidity of motion; and its strength is so prodigious, that the lion contends with it in vain. Mr. Drummond, in his excursions over the Rocky Mountains, had frequent opportunities of observing the manners of the Grizzly Bears, and it often happened that in turning the point of a rock or sharp angle of a valley, he came suddenly upon one or more of them. On such occasions they reared on their hind legs, and made a loud noise like a person breathing quick, but much harsher. He kept his ground, without attempting to molest them; and they on their part, after attentively regarding him for some time, generally wheeled round and galloped off; though, from their known disposition, there is little doubt that he would have been torn in pieces, had he lost his presence of mind and attempted to fly.

THE POLAR BEAR. (*Thalassarctos maritimus*.) The accounts given by the early navigators of the size, strength, and ferocity of the Polar Bear are perfectly appalling; but the accuracy of modern investigation has dissipated many of the erroneous ideas which were formerly entertained on the subject, though it is still very clear that this Bear is possessed of immense strength and fierceness. The whole animal is white, except the tip of the nose and the claws, which are jet

POLAR BEAR
(*THALASSARCTOS MARITIMUS*.)

black; the ears are small and rounded, the eyes small, the teeth very large, and the limbs extremely large and strong. The shores of Hudson's Bay, Greenland, and Spitzbergen, are its principal places of residence; but it has sometimes been accidentally carried on floating ice as far south as Newfoundland. Their usual food consists of seals, fish, and carcasses of whales; but when on land they prey on various animals, as hares, young birds, &c.: they also eat such roots and berries as they can find. They are said to be frequently seen in Greenland in great droves, allured by the scent of the flesh of seals, and will sometimes surround the habitations of the natives, and attempt to break in. Captain Lyon gives the following account of its hunting the seal: "The bear on seeing his intended prey, gets quietly into the water, and swims until to leeward of him, from whence, by frequent short dives he silently makes his approaches, and so arranges his distance, that, at the last dive, he comes to the spot where the seal is lying. If the poor animal attempts to escape by rolling into the water, he falls

into the bear's clutches; if, on the contrary, he lies still, his destroyer makes a powerful spring, kills him on the ice, and devours him at leisure."

During the summer they reside chiefly on the ice-islands, and pass frequently from one to another, being extremely expert swimmers. They lodge in dens, formed in the vast masses of ice, which are piled in a stupendous manner, leaving great caverns beneath: here they breed, and bring forth one or two at a time; and the affection between the parent and the cubs is so great, that they will sooner die than desert each other. During winter they retire, and bed themselves deep beneath the snow, or else beneath the fixed ice of some eminence, where they pass in a state of torpidity the long and dismal arctic night, appearing only with the return of the sun.

JUGGLER BEAR, or JUNGLE BEAR. (*Prochilus ursinus*.) When this uncouth animal was first brought to England (now more than half a century since), it was taken for a Sloth, and obtained the names of *Bradypus pentadactylus*, and *Bradypus ur-*

JUGGLER BEAR. — (*PROCHILUS URSINUS*.)

inus, "Five-fingered Sloth," "Ursine Sloth," and "anonymous animal." It is the *Ours jongleur* of the French, who so called it on account of its being a favourite with the Indian mountebanks or jugglers, who rely on the attraction of its ugliness. The Juggler Bear inhabits the mountainous parts of India, its place of retreat being in some cavern. Its short limbs, the depressed air of the head, surmounted by the hump of a back, and the whole contour of the apparently unwieldy mass, give the idea of deformity. In bulk it is about the size of the Brown Bear. The nasal cartilage is capable of considerable extension, and the lips of protrusion. The muzzle and tips of the paws are a whitish-yellow; and there is a half-collar or Y-like marking on the under side of the neck and breast. With these exceptions, the fur is deep black, with here and there some brown spots, and is rather long, particularly round the head, as the animal grows old. In a state of nature its food consists of fruits, honey, and those destructive insects the white ants. In captivity it appears to be mild, but melancholy.

MALAY BEAR. (*Prochilus Malayanus*.) This animal is jet black, with the muzzle of a yellowish tint, and a crescent-shaped white mark on the breast. Vegetables form

its chief diet, but it is said to be extremely fond of delicacies, and in its native forests subsists in a great measure upon the honey which is there found in considerable abundance. It is attracted to the vicinity of man by its fondness for the young shoots of the cocoa-nut trees, to which it is very injurious. It has been frequently taken and domesticated. One which Sir Stamford Raffles possessed when young is thus described by him: "He was brought up in the nursery with the children; and, when admitted to my table, as was frequently the case, gave a proof of his taste by refusing to eat any fruit

MALAY BEAR. — (PROCYON MALAYANUS.)

but mangosteens, or to drink any wine but champagne. The only time I ever knew him to be out of humour was on an occasion when no champagne was forthcoming. He was naturally of an affectionate disposition, and it was never found necessary to chain or chastise him. It was usual for this bear, the cat, the dog, and a small blue mountain bird or lory of New Holland, to mess together, and eat out of the same dish. His favourite playfellow was the dog, whose teasing and worrying were always borne and returned with the utmost good humour and playfulness. As he grew up he became a very powerful animal, and in his rambles in the garden he would lay hold of the largest plantains, the stems of which he could scarcely embrace, and tear them up by the roots."

BEAVER. (*Castor fiber*.) The Beaver is a Rodent animal, readily distinguished from every other quadruped by its broad horizontally-flattened tail, which is of a nearly oval form, but rising into a slight convexity on its upper surface, and covered with scales. The hind feet are webbed, and together with the tail, which acts as a rudder, serve to propel it through the water with considerable facility. It is about three feet long, exclusive of the tail, which is one foot more: its colour is a deep chestnut, the hair very fine, smooth, and glossy; but it occasionally varies, and is sometimes found perfectly black. The incisor teeth are very large and hard; so hard, indeed, that they were used by the North American Indians to cut bone and to fashion their horn-tipped spears, till they were superseded by the introduction of iron tools from Europe.

Of all quadrupeds the Beaver is considered as possessing the greatest degree of natural or instinctive sagacity in constructing its

habitation; preparing, in concert with others of its own species, a kind of arched caverns or domes, supported by a foundation of strong pillars, and lined or plastered internally with a degree of neatness and accuracy unequalled by the art of any other quadruped. But it should seem, however, that the architecture of the Beaver is nowhere so conspicuous as in the northern parts of America. The favourite resorts of the Beaver are retired, watery, and woody situations. In such places they assemble, to the number of some hundreds; living, as it were, in families, and building their arched receptacles. From this we may perceive to what a degree animals, unassisted either by language or reason, are capable of concurring for their mutual benefit, and of attaining, by dint of numbers, those advantages which each, in a state of solitude, seems unfitted to possess: for if we view the Beaver only in the light of an individual, and unconnected with others of its kind, we shall find that many other quadrupeds excel it in cunning, and almost in all the powers of annoyance and defence. When kept in a state of solitude or domestic tameness, it appears calm and indifferent to all about it; without attachments or antipathies; and never seeking to gain the favour of man, nor aiming to offend him.

BEAVER. — (CASTOR FIBER.)

Few subjects in natural history have more attracted the attention of travellers, or have been more minutely described by naturalists, than the instinctive building operations of the Beaver; and they have accordingly had attributed to them powers so marvellous, as to render ridiculous that which, if regarded merely as a high species of animal instinct, could not fail to command universal admiration. The account given by Buffon, though graphic and amusing in no ordinary degree, is evidently overcharged: we shall therefore take the more sober narration of Hearne: "The situation of the beaver-houses is various. Where the beavers are numerous they are found to inhabit lakes, ponds, and rivers, as well as those narrow creeks which connect the numerous lakes with which this country abounds; but the two latter are generally chosen by them when the depth of water and other circumstances are suitable, as they have then the advantage of a current to convey wood and other necessities to their habitations, and because, in general, they are more difficult to be taken than those that are built in standing water. They always choose those parts that have such a depth of water as will resist the frost in winter, and prevent it from freezing to the

bottom. The beavers that build their houses in small rivers, or creeks, in which water is liable to be drained off when the back supplies are dried up by the frost, are wonderfully taught by instinct to provide against that evil by making a dam quite across the river, at a convenient distance from their houses. The beaver-dams differ in shape according to the nature of the place in which they are built. If the water in the river, or creek, have but little motion, the dam is almost straight; but where the current is more rapid, it is always made with a considerable curve, convex toward the stream. The materials made use of are drift-wood, green willows, birch, and poplars if they can be got; also mud and stones intermixed in such a manner as must evidently contribute to the strength of the dam; but there is no other order or method observed in the dams, except that of the work being carried on with a regular sweep, and all the parts being made of equal strength. In places which have been long frequented by beavers undisturbed, their dams, by frequent repairing, become a solid bank, capable of resisting a great force both of water and ice; and as the willow, poplar, and birch generally take root and shoot up, they by degrees form a kind of regular planted hedge, which I have seen in some places so tall that birds have built their nests among the branches.

"The beaver-houses are built of the same materials as their dams, and are always proportioned in size to the number of inhabitants, which seldom exceeds four old and six or eight young ones; though, by chance, I have seen double the number. Instead of order or regulation being observed in rearing their houses, they are of a much ruder structure than their dams; for, notwithstanding the sagacity of these animals, it has never been observed that they aim at any other convenience in their houses than to have a dry place to lie on; and there they usually eat their victuals, which they occasionally take out of the water. It frequently happens that some of the large houses are found to have one or more partitions, if they deserve that appellation, but it is no more than a part of the main building left by the sagacity of the beaver to support the roof. On such occasions it is common for those different apartments, as some are pleased to call them, to have no communication with each other but by water; so that, in fact, they may be called double or treble houses, rather than different apartments of the same house.

"So far are the beavers from driving stakes into the ground when building their houses, that they lay most of the wood crosswise, and nearly horizontal, and without any other order than that of leaving a hollow or cavity in the middle. When any unnecessary branches project inward they cut them off with their teeth, and throw them in among the rest, to prevent the mud from falling through the roof. It is a mistaken notion that the wood-work is first completed and then plastered; for the whole of their houses, as well as their dams, are, from the foundation, one mass of mud and wood mixed with stones, if they can be procured. The mud

is always taken from the edge of the bank, or the bottom of the creek or pond near the door of the house; and though their forepaws are so small, yet it is held close up between them under their throat: thus they carry both mud and stones, while they always drag the wood with their teeth. All their work is executed in the night, and they are so expeditious that, in the course of one night, I have known them to have collected as much as amounted to some thousands of their little handfuls. It is a great piece of policy in these animals to cover the outside of their houses every fall with fresh mud, and as late as possible in the autumn, even when the frost becomes pretty severe, as by this means it soon freezes as hard as a stone, and prevents their common enemy, the wolverene, from disturbing them during the winter; and as they are frequently seen to walk over their work, and sometimes to give a flap with their tail, particularly when plunging into the water, this has, without doubt, given rise to the vulgar opinion that they used their tails as a trowel, with which they plastered their houses; whereas that flapping of the tail is no more than a custom which they always preserve, even when they become tame and domestic, and more particularly so when they are startled."

In the more northern climates the habitations of these animals are finished in August, or early in September, when they begin to lay in their stores. During the summer months they regale themselves on the choicest fruits and plants the country affords; but in winter they subsist principally on the wood of the birch, the plane, and some other trees, which they steep in fresh water from time to time. Those who are accustomed to hunt these animals, being perfectly aware that green wood is much more grateful to them than that which is old and dry, place a considerable quantity round their lodgments; and when they sally forth to seize it, either catch them in snares, or take them by surprise. When the frost is very severe, the hunters sometimes break large holes in the ice; and, on the Beavers resorting to these apertures to breathe the fresh air, they either kill them with their hatchets, or cover the holes with large substantial nets. This being done, they undermine and subvert the whole fabric; when the beavers, expecting to make their escape in the usual way, fly with precipitation to the water, and, rushing to the opening, fall directly into the net.

The Beaver is pursued both for its fur, and for the sake of a peculiar odoriferous secretion, termed *castor*, or *castoreum*, which is contained in two little bags, the inguinal glands, each about the size of a hen's egg. This substance, as we find it in the shops, is of a brownish unctuous consistence, has a disagreeable narcotic smell, and a nauseous acrid taste; it was at one time esteemed as possessing considerable medicinal properties, but is now chiefly employed by perfumers. The fur was formerly a most important article of commerce; but the animals have in recent times been exterminated from so many extensive tracts which they once in-

habited, that it is now far less considerable than it was half a century ago. To this may be added, that the present custom of using silk and other materials in lieu of beavers' fur in the manufacture of hats, has wonderfully lessened the demand for it, as well as reduced the price. An idea, however, may be formed of the astonishing number of beavers' skins that were formerly made use of, when we state that in 1808, no less than 126,927 were sent from Quebec alone to this country. The flesh of the Beaver is much prized by the Indians and Canadian voyagers, especially when it is roasted in the skin after the hair has been singed off: and in some districts it requires all the influence of the fur-traders to restrain the hunters from sacrificing a considerable quantity of beaver fur every year to secure the enjoyment of this luxury; and Indians of note have generally one or two feasts in a season, wherein a roasted beaver is the prime dish. It resembles pork in its flavour, but it requires a strong stomach to sustain a full meal of it. (*Richardson's Fauna boreali-Americana.*)

Our readers will see that the foregoing account relates to the American Beaver. The European species does not boast of such architectural habits, but lives in burrows along the banks of the Rhone, the Danube, the Weser, and other large rivers in the north of Europe; yet, from some of the descriptions which have been given of them, we are disposed to believe that, considering the materials within their reach, their instinctive skill is not greatly inferior to those who dwell on the other side of the Atlantic. It is believed that at no period were Beavers common in Britain, though the mention of them by some of our earliest historians is a clear proof of their existence here.

BECCAFIGO, or FIG-EATER. (*Sylvia hortensis.*) A migratory song-bird, about the size of a linnet, but with a remarkably short body. It feeds on fruits and berries, and is highly prized by the Italians for the delicacy of its flesh, particularly in autumn, when it is in excellent condition for the table. It is often seen in England in the summer, where it is called the Pettychaps; but it generally returns to a warmer climate in September. It has a lively, loud, and piercing note; but it is seldom seen, as it usually sings from the midst of some closely embowered covert. Its head, back, neck, wings, and tail are generally of a greenish grey, but some more incline to a greenish brown.

BEE. (*Apis.*) The generic name of a family of Hymenopterous insects, [for the classification of which, see *APIDÆ.*] Of all the insect tribe none have more justly excited the attention and admiration of mankind than the Bee; and yet, although it has engaged the study of naturalists for two thousand years, we still occasionally find, in the economy of this social and industrious little animal, some obscurely known or unelucidated fact, which is thought worthy of the labours of those who devote their time and abilities in the pursuit and advancement of this interesting branch of natural science.

The most important species is the **HONEY-BEE** (*Apis mellifica*), so long celebrated for its wonderful polity, the neatness and precision with which it constructs its cells, and the diligence with which it provides during the warmth of summer a supply of food for the support of the hive during the rigours of the succeeding winter. In its natural state the Honey-bee generally constructs its nests in hollow trees; but so universally is it now domesticated that we rarely find it otherwise than hived in any part of Europe.

Peter Kalm, the Swedish traveller, observes, that the people of North America were unanimously of opinion that the

HONEY-BEE. — (*APIS MELLIFICA.*)

Honey-bee was unknown in that country before the arrival of the Europeans; but that they were first brought over by the English who settled there. The Indians likewise declared that their fathers had never seen any bees either in the woods or elsewhere, before the Europeans had been several years settled there. This, he says, is further confirmed by the name which the Indians gave them: for, having no particular name for them in their language, they call them *English flies*, because the English first brought them over; but at the time he wrote (nearly a century ago) they flew plentifully about the woods of North America.

Honey and wax are the two valuable articles of commerce for which we are indebted to this useful insect. Now, if we examine the structure of the common Bee, the first remarkable part which presents itself is the proboscis, an instrument serving to extract honey from flowers: it is not formed, like that of other flies, in the shape of a tube, by which the fluid is to be sucked up, but rather like a tongue, to lap it up. When thus lapped out of the nectary, it is conveyed to the crop or honey-bag; where it undergoes but little alteration, and is transferred or disgorged into the cells destined to receive it. While the Bee is busy in extracting the sweets of the flowers, it becomes covered with the farina or pollen of the anthers; this pollen it wipes off with the brushes of its legs, collects every particle together, and kneads it into two little masses, which it lodges on the broad surface of the tibia of each hind leg, where a series of elastic hairs over-arches a concavity, and acts as a sort of lid or covering. Thus employed, the Bee flies from flower to flower, increasing its store of honey, and adding to its stock of kneaded pollen, which is called *bee-bread*. The abdomen is divided into six annulations or rings, which are capable of being contracted or extended at pleasure; and the insect is internally furnished with a honey-bag, a

venom-bag, and a sting. The honey-bag, which is as transparent as crystal, contains the honey which the Bee has brushed from the flowers, the greatest part of which is carried to the hive, and poured into the cells of the honeycomb, while the remainder serves for the Bee's own nourishment. Wax is a peculiar secretion in little cells beneath the scales of the abdomen. It is from honey that the wax, by some internal process, is elaborated. The wax oozes out between the abdominal rings, in the form of little linnæ; it is then worked with the mouth, and kneaded with saliva that it may acquire the requisite degree of ductility for the construction of the comb, which is finished with a substance called *propolis*, a glutinous or gummy resinous matter procured from the barks of certain trees.

The *sting* is composed of three parts; namely, the sheath, and two extremely small and penetrating darts, each of which is furnished with several points, or harbs, which, rankling in the wound, render the sting more painful. This instrument, however, would prove but a feeble weapon, if the Bee did not poison the wound. The sharp-pointed sheath first enters, and this being followed by the barbed darts, the venomous fluid is speedily injected. Sometimes the sting sticks fast in the flesh, and is left behind; but the death of the Bee invariably follows.

Having examined the Bee singly, we now proceed to an inquiry into its habits as a member of a social community. Viewed in this light, we behold an animal active, vigilant, laborious, and disinterested; subject to regulations, and perfectly submissive. All its provisions are laid up for the community; and all its arts are employed in building a cell, designed for the benefit of posterity. Many interesting accounts of the history and economy of the Bee have been published. We know of none, however, so concise and at the same time so explicit, as that which is given by Mr. Newman, in his "Familiar Introduction to the Study of Insects;" and to that source we are indebted for the following observations, marked with inverted commas:—

"A bee-hive contains three kinds of individuals,—a queen, drones, and workers; the queen is a female, and not only the ruler, but, in great part, the mother of the community; the drones are males, and the workers are abortive females. The sole office of the queen appears to be the laying of eggs, and this occupies her almost incessantly, as a single one only is deposited in each cell, thus causing her to be in continual motion; she is slow and majestic in her movements, and differs from the workers in being larger, having a longer body, shorter wings, and a curved sting. The queen is accompanied by a guard of twelve workers, an office which is taken in turn, but never intermitted; in whatever direction she wishes to travel, these guards clear the way before her, always with the utmost courtesy turning their faces towards her, and when she rests from her labours, approaching her with humility, licking her face, mouth, and eyes,

and appearing to fondle her with their antennæ.

"The drones are all males; they are less than the queen, but larger than the workers; they live on the honey of flowers, but bring none home, and are wholly useless, except as being the fathers of the future progeny: when this office is accomplished, they are destroyed by the workers. A buzzing commences in the hive, the drones and the workers rally forth together, grapple each other in the air, hug and scuffle for a minute, during which operation the stings of the workers are plunged into the sides of the drones, who, overpowered by the poison, almost instantly die.

"The workers are the smallest bees in the hive, and by far the most numerous; they have a longer lip for sucking honey than either of the others; their thighs are furnished with a brush for the reception of the pollen of flowers, and their sting is straight. The workers do the entire work of the community; they build the cells, guard the hive and the queen, collect and store the honey, elaborate the wax, feed the young, kill the drones, &c. The average number of these three kinds of bees in a hive is one queen, 2000 drones, and 20,000 workers. The eggs are long, slightly curved, and of a bluish colour; when laid they are covered with a glutinous matter, which instantly dries, attaching them to the bottom of the cell.

"For eleven months the queen lays only workers' eggs; afterwards, those which produce drones: as soon as this change has taken place, the workers begin to construct royal cells, in which, without discontinuing to lay the drones' eggs, the queen deposits here and there, about once in three days, an egg which is destined to produce a queen. The workers' eggs hatch in a few days, and produce little white maggots, which immediately open their mouths to be fed; these the workers attend to with untiring assiduity: in six days each maggot fills up its cell; it is then roofed in by the workers, spins a silken cocoon, and becomes a chrysalis: and on the twenty-first day it comes forth a perfect bee. The drones emerge on the twenty-fifth day, and the queens on the sixteenth."

When the queen-bee has an inclination to deposit her eggs, she goes forth, accompanied by six or eight working bees as a guard, whose stomachs are filled with honey. She is very deliberate in her motions, and seems to proceed with great caution. She first looks into a cell, and if she finds it perfectly empty, she draws up her long body, inserts her tail into the cell, and deposits an egg. In this way she slowly proceeds till she has dropped ten or twelve eggs, when perhaps feeling exhausted, she is fed by one of the attendant bees, who have surrounded her the whole time. This is done by the bee ejecting the honey from its stomach into the mouth of the queen. When this has been done, the bee goes away, and another takes its place. The operation of laying her eggs again goes on, and is succeeded by the same mode of feeding,—the attendant bees frequently touching the antennæ of the queen

with their own. When the operation of laying the eggs is completed,—and it generally occupies some time,—the queen retires to that part of the hive which is most filled with bees. During her progress the surface of the comb is very little intruded upon, and the space seems purposely to be left unoccupied. Some few of the cells, however, in a brood comb, are passed over by the queen, and afterwards filled either with honey or farina. These serve as deposits of food, from which the neighbouring brood may be fed more readily, as such cells are never covered with wax. — *Jesse.*

"It has been already stated, that the queen, for nearly a year, lays no eggs that are destined to produce queens; it therefore follows, that if any evil befall her, the hive is left without a queen: it sometimes happens that she dies, or is taken away by the owner of the hive, to observe the result. For twelve hours little notice is taken of the loss; it appears not to be known, and the workers labour as usual: after that period, a hubbub commences; work is abandoned; the whole hive is in an uproar; every bee traverses the hive at random, and with the most evident want of purpose. This state of anarchy sometimes continues for two days; then the bees gather in clusters of a dozen or so, as though engaged in consultation, the result of which seems to be a fixed resolution to supply the loss. A few of the workers repair to the cells in which are deposited the eggs of workers; three of these cells are quickly broken into one, the edges polished, and the sides smoothed and rounded, a single egg being allowed to remain at the bottom. When this egg hatches, the maggot is fed with a peculiarly nutritive food, called royal bee-bread, which is never given to any maggots but such as are to produce queens; work is now resumed over the whole hive, and goes on as briskly as before: on the sixteenth day the egg produces a queen, whose appearance is hailed with every demonstration of delight, and who at once assumes sovereignty over the hive. When, under ordinary circumstances, a young queen emerges from the chrysalis, the old one frequently quits the hive, heading the first swarm for the season, and flying to some neighbouring resting-place, is observed by the owner, captured, placed under a new hive, and a new colony is immediately commenced. Before a swarm leaves the hive, sure indications are given of the intended movement; the workers leave their various occupations and collect in groups, especially near the door of the hive, as though in consultation on the important event about to take place.

"As the summer advances many queens are hatched, but the workers do not allow them instant liberty, as severe battles would take place between them and the reigning queen, in which one would be killed: the workers, therefore, make a small hole in the ceiling of the royal cell, through which the captive queen thrusts her tongue, and receives food from the workers. In this state of confinement the young queen utters a low querulous note, which has been compared to

singing. When the reigning, or a newly-created queen, finds one of these captives, she uses every effort to tear open the cell and destroy her rival: to prevent this, the workers often interpose, pulling her away by the legs and wings; to this she submits for a short time, when, uttering a peculiar cry, called her voice of sovereignty, she commands instant attention and obedience, and is at once freed from her assailants. The cocoons spun by the maggots of the workers and drones completely envelope the chrysalis; but that spun by the maggot of the queen appears imperfect, covering only the upper end of the chrysalis: it has been supposed that they are thus designedly exposed to the attacks of other queens, and their destruction, before emerging, facilitated. When the chrysalis of the queen is about to change to a perfect insect, the bees make the cover of the cell thinner by gnawing away part of the wax; and with so much nicety do they perform this operation, that the cover at last becomes pellucid, owing to its extreme thinness.

"The combs of a bee-hive comprise a congeries of hexagonal cells, built by the bees as a receptacle for honey, and for the nurseries of their young: each comb in a hive is composed of two ranges of cells, backed against each other: the base or partition between this double row of cells is so disposed as to form a pyramidal cavity at the bottom of each. There is a continued series of these double combs in every well-filled hive; the spaces between them being just sufficient to allow two bees, one on the surface of each comb, to pass without touching. Each cell is hexagonal, the six sides being perfectly equal. This figure ensures the greatest possible economy of material and space; the outer edges of the cells are slightly thickened, in order to gain strength; the same part is also covered with a beautiful varnish, which is supposed to give additional strength. The construction of several combs is generally going on at the same time: no sooner is the foundation of one laid, with a few rows of cells attached to it, than a second and a third are founded on each side, parallel to the first, and so on till the hive is filled, the combs which were commenced first being always in the most advanced state, and therefore the first completed.

"The design of every comb is sketched out, and the first rudiments laid by a single bee: this foundress-bee forms a block out of a rough mass of wax, drawn partly from its own resources, but principally from those of other bees, which furnish wax from small sacs, in which it has been secreted, that are situated between the segments of the body of the bee; taking out the plates of wax with their hind feet, and carrying it with their fore feet to their mouths, where it is moistened, masticated, and rendered soft and ductile. The foundress-bee determines the relative position of the combs, and their distance from each other, the foundations which she marks serving as guides to the ulterior labours of the wax-working bees, and of those which build the cells, giving them the advantage of the margins and

angles already formed. The mass of wax prepared by the assistants is applied by the foundress-bee to the roof or bottom of the hive, and thus a slightly double convex mass is formed: when of sufficient size, a cell is sculptured on one side of it by the bees, who relieve one another in the labour. At the back, and on each side of this first cell, two others are sketched out and excavated: by this proceeding the foundations of two cells are laid, the line betwixt them corresponding with the centre of the opposite cells: as the comb extends, the first excavations are reentered deeper and broader; and when a pyramidal base is finished, the bees build up walls from its edges, so as to complete what may be called the prismatic part of the cell. The cells intended for the drones are considerably larger and more substantial than those for the workers; and being formed subsequently, they usually appear nearer the bottom of the combs: last of all are built the royal cells for the queecs: of these there are usually three or four, sometimes ten or twelve, in a hive, attached completely to the central part, but not unfrequently to the edge of the comb. The form of the royal cells is an oblong spheroid, tapering gradually downwards, and having the exterior full of holes: the mouth of the cell, which is always at the bottom, remains open until the maggot is ready for transformation, and it is then closed like the rest.

"When a queen has emerged, the cell in which she was reared is destroyed, and its place is supplied by a range of common cells: the site of this range may always be traced by that part of the comb being thicker than the rest, and forming a kind of knot. The common breedlog cells of droocs and workers are occasionally made the depositories of honey; but the cells are never sufficiently cleansed to preserve the honey undeteriorated. The finest honey is stored in new cells constructed for the purpose of receiving it, their form precisely resembling that of the common breeding cells: these honey-cells vary in size, being larger or smaller according to the productiveness of the sources from which the bees are collecting, and according to the season."

It is remarkable that all animals which have been long under the protection of man seem to lose a part of their natural sagacity. In those countries where the bees are wild, and unprotected by man, they are always sure to build their waxen cells in the hollows of trees; but with us they appear improvident to their choice; and the first green branch which stops their flight is deemed sufficient for their abode. It does not even appear that the queen chooses the place where they are to alight; for numbers of the swarms when they conceive a predilection for any particular branch, spontaneously settle on it; others follow their example; and at last the queen herself, finding the majority of the swarm convened together, condescends to place herself amongst them. The queeo being settled, the rest of the swarm soon flock around her, and in about a quarter of an hour the whole body seems to be perfectly at rest.

When a hive sends out several swarms in a year, the first is always the best as well as the most numerous; for, having the greatest part of the summer before them, they have the more time for making wax and honey, and consequently their labours are the most valuable to their proprietor. Though the swarm is principally made up of the younger bees, those of all ages geocerally compose the number of emigrants; and as a single hive sometimes contains upwards of forty thousand inhabitants, such a vast body may well be supposed to work with great expedition.

Among the varied mass of amusing and instructive information with which the volumes of Kirby and Speoce abound, we shall make a few condensed extracts ere we close this article:—Bees to their exccorsious do not confioe themselves to the spot immediately contiguous to their dwelling, hut, when led by the scent of honey, will go a mile from it, or considerably more; yet from this distance they will discover honey with as much certainty as if it was within their sight. * * * A new-born bee, as soon as it is able to use its wings, seems perfectly aware, without any previous instruction, what are to be its duties and employments for the rest of its life. It appears to know that it is born for society, and not for selfish pursuits; and therefore it invariably devotes itself and its labours to the benefit of the community to which it belongs. Walking upon the combs, it seeks for the door of the hive, that it may sally forth and be useful. Full of life and activity, it then takes its first flight; and, unconducted but by its instinct, visits like the rest the subjects of Flora, absorbs their nectar, covers itself with their ambrosial dust, which it kneads into a mass and packs upon its hind legs; and, if need be, gathers propolis (an uctionous resinous substance, collected from the buds of trees, and used in lining the cells of a new comb, stopping crevices, &c.), and returns unembarrassed to its own hive.

The method of ventilating their hives is thus described:—By means of their marginal hooks, they unite each pair of wings into one plane slightly concave, thus acting upon the air by a surface nearly as large as possible, and forming for them a pair of very ample fans, which in their vibrations describe an arch of 90°. These vibrations are so rapid as to render the wings almost invisible. During the summer a certain number of workers—for it is to the workers solely that this office is committed—may always be observed vibrating their wings before the entrance of their hive; and the observant apiarist will find, upon examination, that a still greater number are engaged within it in the same employment. The station of these ventilators is upon the floor of the hive. They are usually ranged in files that terminate at the entrance; and sometimes, but not constantly, form so many diverging rays, probably to give room for comers and goers to pass. The number of ventilators in action at the same time varies: it seldom much exceeds twenty, and is often more circumscribed. The time also that they devote to this function is longer or

shorter, according to circumstances: some have been observed to continue their vibrations for nearly half an hour without resting, suspending the action for not more than an instant, as it should seem to take breath. When one retires, another occupies its place; so that in a hive well peopled there is never any interruption of the sound or humming occasioned by this action, by which it may always be known whether it be going on or not. [For Reproduction of Bees, see PARTHENOGENESIS in SUPPL.]

BEE-EATER. (*Merops*.) There are many species of this genus, all being distinguished by brilliant plumage; they take their prey, consisting of bees, wasps, gnats, &c., on the wing, like the swallow, and without being stung by them. The one we are about to describe is among the most elegant of the European birds, and, next to the Roller and the Kingfisher, may be considered as the most brilliant in point of colour. It is a native of the warmer parts of Europe, particularly among the islands of the Grecian archipelago, and of many parts both of Asia and Africa; but in the north of Europe it is rarely seen. In shape this bird resembles the balcyon tribe, and is about the size of a blackbird. The bill is slightly curved, sharp-pointed, rather long, and black; the irides bright red; the crown

BEE-EATER — (*MEROPS APIASTER*)

of the head and upper parts of the neck and back are of an orange-chesnut colour; the throat yellow, the scapulars, lower part of the back, and wing-coverts pale yellow, more or less shaded with an admixture of red and green. The smaller quill feathers are rufous chesnut, tipped with green; the larger sea-green with dusky tips; the rump and tail sea-green, the latter about three inches long, the two middle feathers projecting, in a pointed form, to some distance beyond the rest. The sides of the head, above the eyes, and the whole under parts are sea-green; from the corners of the bill, on each side of the head, a black streak passes across the eyes, curving downwards, and nearly meeting the tips of a black crescent placed across the snout, and separating the yellow of that part from the sea-green of the under parts. The legs are short, and of a reddish-brown colour. It builds in deep holes in the banks of rivers, forming

a nest of moss, and laying from five to seven white eggs.

The **INDIAN BEE-EATER** (*Merops viridis*) is about half the size of the common or European Bee-eater, but the middle tail-feathers are considerably longer. On the upper part of the breast is a crescent-shaped transverse mark, with the horns pointing upwards; the back and lesser covert-feathers of the wings are of a parrot-green colour; the rump or coverts of the tail of a bluish-green; the breast and belly of a light green, and the tail is green. The greater quills of the wings are dusky at their tips; the centre quills are of an orange colour, bordered with green, and marked with black spots, the extreme tips being orange; the interior quills next the back are wholly green; the first row of coverts above the quills is orange in the centre, and green on the edges. The bill is long and sharp-pointed, having a downward incurvature; the claws are pretty strong; and the legs and feet of a dusky brown colour. This species is a native of Bengal, parts of Madagascar, &c.

BEETLES. The insects composing the order **COLEOPTERA**, or Beetles, are almost incredible in point of number, as may readily be supposed when it is stated that between 70,000 and 80,000 species at present exist in the cabinets of collectors. The singular forms and brilliant colours of many of them; the size of their bodies; the solid texture of their integuments, which renders their preservation comparatively easy; and the nature of their habits, which affords every facility for their capture; have combined to render them objects of peculiar attention to those who delight in the science of entomology.

Among the beetle tribe some are very remarkable for projections or horns growing from the head and corselet. The species found in warm climates are generally large and of a formidable appearance, though by no means noxious. They are mostly winged, flying with much rapidity and force; but when on the ground their movements are slow and heavy. The wings of beetles are covered and concealed by a pair of horny cases or shells, meeting in a straight line on the top of the back, and usually having a little triangular or semicircular piece, called the scutellum, wedged between their bases. Hence the order to which these insects belong is called *Coleoptera*, a word signifying wings in a sheath. They are all produced from eggs; they then become grubs; afterwards they are changed into chrysalides; and lastly, the beetles, leaving their prisons, sally forth as winged insects in full maturity. The conversion of the first pair of wings into *elytra*, or hard wing-cases, and the complete inclosure of the second pair by these, when the insect is at rest, constitute the distinguishing features of the order. The *elytra*, when expanded, are of little or no use in flight, generally remaining nearly motionless; when closed, they meet along the back in a straight line, which is called the suture. The body of the perfect insect is oval, or nearly so, and the head is pro-

vided with two antennæ, composed of eight or ten pieces; the extremities of the antennæ are club-shaped, and composed of plates or joints, either disposed like the leaves of a book, or arranged perpendicularly to the axis, like the teeth of a comb. The eyes are large and protuberant, especially in the carnivorous species, and in those, the slowness of whose habits makes them need quick powers of sight, for the purpose of avoiding their enemies. Of the three segments of the thorax, the corslet greatly surpasses the two others in size; and the chief movement of the parts of the trunk upon one another, is between the first and second segments of the thorax. The two fore-legs of beetles, and even the others, in some instances, are denated externally, and suited for burrowing. These are the principal characters which distinguish this numerous family; but it is necessary to observe that nearly all of them are subject to some exceptions.

The larvæ are soft, flexible, whitish, semi-cylindric worms, having the body divided into twelve rings, and having a scaly head, armed with strong jaws. They have nine *stigmata*, or breathing-holes, on each side; and the feet, which are six, are scaly. The body is thicker at the posterior than at the anterior extremity, and rounded, almost uniformly curved downwards, so that the larva moves with difficulty over an even surface, and frequently tumbles down. The period during which the larvæ remain in the state of destructive worms, varies in different species; those of some kinds becoming nymphs at the end of several months, and of others not sooner than three or four years. During this period they live in the earth, where they feed upon the roots of vegetables, animal matter in a state of decomposition, &c. It is in this stage of their existence that various species prove exceedingly injurious to farmers and gardeners, from their great numbers and voracity. When about to undergo their change of form, they make an egg-shaped cocoon, from fragments gnawed off wood, &c., which are united by a peculiar glutinous fluid furnished by their bodies. The form of the future beetle is now plainly perceived, the different parts being encased in distinct sheaths. Though the varieties of this genus arising from size and colour are wonderful—some being no larger than a pin's head, while others are several inches in length and circumference,—their most essential difference proceeds from the stages of their existence, some undergoing all their transformations in a few months, and others requiring nearly four years to complete their production.

BELEMNITES. A genus of fossil Cephalopoda, which at different periods have received the names of *Thunderstone*, *Arrow-head*, and *Fingerstone*. The name is derived from *Belemn* (Gr.), a dart or arrow. They abound in several of the older rocks, especially the lias and oolite; and consist of an interior cone divided into partitions connected by a syphon, as in the Nautilus, and surrounded by a number of concentric layers, made up of fibres radiating from the axis.

BELEMNITE.
(B. AOUTAS.)

BELEMNITE
[RESTORED.]

These layers are somewhat transparent, and when burnt, rubbed, or scraped, give the odour of rasped horn. From the weight of its dense internal shell the Belemnite may be supposed to have usually maintained a vertical position; and as its chambered portion was provided with a siphuncle analogous to that which we find in the Nautilus, the animal probably had the power of ascending and descending in the water with facility. The animal, of which the Belemnite was the internal "bone," has been proved by Mr. Owen to have been a dibranchiate eight-armed Cattle-fish, somewhat resembling the recent genus *Onychoteuthis*. This he was enabled to do by access to specimens found near Chippenham, in Wiltshire, during the excavations that were making for the Great Western Railway. The species are now extinct.

BELL-BIRD. (*Procnias carunculata*.) This is a species of Chatterer, distinguished by a long soft caruncle at the base of its beak; it is white when adult, greenish when

BELL-BIRD.—(*PROCNIAS CARUNOULATA*.)

young. It is a native of South America—the celebrated Campanero or Bell-bird of Guiana—the loud sonorous voice of which, heard from time to time in the depths of the forest, during the stillness of mid-day, exactly resembles the tolling of a bell.

Mr. Waterton, in his hearty "Wanderings in Demerara," often alludes to it. In one passage he says that it "never fails to attract

the attention of the passenger ; at a distance of nearly three miles you may hear this snow-white bird tolling every four or five minutes like the distant convent bell. From six to nine in the morning the forests resound with the mingled cries and strains of the feathered race, after this they gradually die away. From eleven to three, all nature is hushed as in a midnight silence, and scarce a note is heard, saving that of the *companero* of the *pi-pi-yo* ; it is then that, oppressed by the solar heat, the birds retire to the thickest shade, and wait for the refreshing cool of the evening."

BELLEROPHON. A genus of fossil shells, the animals of which are unknown, but which are now generally supposed to have been allied to *Cariuaria*, the structure of whose shell it resembles.

BELODON. A title given by Von Meyer to a genus of extinct reptiles found in the upper white cretaceous sandstone in the neighbourhood of Wirtemberg. The species appear to be closely allied to the great Dinosaurs of the oolite.

BELONE. A genus of fishes remarkable for the bright green colour of their bones. The jaws are much extended, and furnished with small teeth, without any others in the mouth, except in the pharynx. The body is very long, and covered with scales which are scarcely visible, except one keeled row on each side, near the under edge of the fish. [See GARFISH.]

BELUGA. (*Delphinus leucos.*) A Cetaceous animal, of the size of the Grampus. It chiefly inhabits the seas of the Arctic regions, but is sometimes met with even on the British coasts. [See WHALE.] It is also the Russian name for the largest species of Sturgeon (*Acipenser huso*).

BELYTA. A genus of Hymenopterous insects, being a species of minute four-winged flies, which frequent sandy situations.

BEMBEX: BEMBEDIDÆ. A genus and family of Hymenopterous insects, peculiar to hot climates, and, in some instances, very much resembling wasps both in size and colour. *Bembex rostrata*, an insect about the size of a wasp, is the type of this family, and is remarkable for having the lower parts of the mouth produced into a long trunk or proboscis. The female forms oblique cylindrical burrows in sandy banks, with a cell at the end of each, and having collected five or six flies, and placed them in her cell, she deposits a single egg in it ; then having carefully closed its mouth, she proceeds in the same manner with another cell. These flies are no sooner hatched than the larva devours them ; it then changes into the pupa state, and shortly after to the perfect insect.

BEMBEDIDÆ. A family of minute carnivorous beetles, which generally frequent damp situations, such as the banks of rivers, ditches, &c. They are usually of a bright blue or green metallic colour, having two or four pale yellow spots on the elytra.

BERNACLE or BARNACLE GOOSE. (*Bernicla leucopsis*). A bird which inhabits the arctic regions, and in its autumnal and brumal migrations visits the more temperate regions of England, France, Germany, Holland, &c. It frequents the north-west coasts of this country, and some parts of Ireland, in large flocks during the winter, but is rarely

BERNACLE GOOSE. (*BERNICLA LEUCOPSIS*.)

seen in the south except in very severe weather. About February it retires to the north to breed, and is then found in Russia, Lapland, Iceland, Spitzbergen, and other high latitudes.

The length of the Bernacle is rather more than two feet. The bill is black, with a reddish streak on each side, and between it and the eyes is a small black streak ; the irides dusky-brown ; the forehead, sides of the head, and the throat, are of a pure white ; the rest of the head, neck, and shoulders black, the upper part of the plumage is marked with blue, grey, black and white ; and the legs are black.

The history of this bird has been rendered singularly remarkable by the marvellous accounts which were related in the darker ages concerning its growth ; it being a received opinion that the Bernacle was produced in a kind of cirripede, the *lepas anatifera* of Linnæus, growing on rotten ship-timber and other kinds of wood, and trees which lay under water on the coasts ! Among these is Gerard, a famous botanist in his day, whose account is too absurd to give in detail, but perhaps a short extract may be tolerated : " When it is perfectly formed, the shell gapeth open, and the first thing that appeareth is the aforesaid lace or string ; next cometh the legs of the bird hanging out ; and as it groweth greater, it openeth the shell by degrees till at length it has all come forth, and bangeeth only by the bill. In short space after it cometh to full maturity, and falleth into the sea, where it gathereth feathers, and groweth to a fowl, bigger than a mallard, and lesser than a goose, having black legs, and bill or beak, and feathers black and white, spotted in such manner as our magpie ! " Again, Sir Robert Murray, in his account inserted in the Philosophical Transactions, says that he

found "an old fir tree on the coast of Scotland, covered with bernacle shells, and that in every shell that he opened he found a perfect sea-fowl; the little bill, like that of a goose; the eyes marked; the head, neck, breast, wings, tail, and feet formed; the feathers every where perfectly shaped, and blackish coloured; and the feet like those of other water-fowl!" Such are some of the wild chimeras that have been handed down concerning the origin of these birds; such the dangerous contagion of the errors of science, where the imagination is allowed to soar beyond the region of common-sense.

There are several other species, some of which we shall briefly describe:—

The RED-BREASTED BERNACLE. (*Bernicla ruficollis*.) This is a beautiful bird, about twenty-two inches in length; the beak is brown, with its hook black; between the beak and the eye is a white space; behind the eyes and on the sides of the neck it is white; the top of the head, the throat, belly, tail, and all the upper parts are deep black; the vent, under tail-coverts, and rump are pure white; but the breast and fore part of the neck are bright red. A band of black extends the entire length of the hinder part of the neck; the greater wing-coverts are tipped with white; and the legs are black. This beautiful bird inhabits the arctic countries of Asia, living on the borders of the Frozen Ocean: it appears periodically in Russia, and occasionally in Germany; but in England it is very rarely seen. A British-killed specimen, however, has been seen by us in the British Museum.

The WHITE-WINGED BERNACLE. (*Bernicla leucoptera*.) This bird varies in length from about thirty-two to forty inches; the head, neck, lesser wing-coverts, and under parts of the body, white; the lower part of the neck behind, and as far as the middle of the back, crossed with numerous dusky-black lines; the two middle tail-feathers black; the rest white; and the legs black. It stands pretty high upon its legs; walks and flies with great ease; and has not that disagreeable cackling cry peculiar to the rest of its kind. The flesh is wholesome and nourishing. It inhabits the Falkland Islands, where it is called the Bustard Goose.

The ANTARCTIC BERNACLE. (*Bernicla Antarctica*.) This is rather smaller than a tame goose: beak narrow, short, and black; the whole plumage of a dazzling snowy whiteness; on the bend of the wing a blunt knob: legs yellow. It inhabits Christmas Sound, in Terra del Fuego. Its flesh is unfit to be eaten.

BEROE. (*Berœ*, or *Cydippe pileus*.) A small marine animal belonging to the class *Acalepha*, and to which the name *Cydippe* is now very frequently applied. This little animal is nearly of a globular form, somewhat elongated, and about three-fourths of an inch in length. It is composed of a gelatinous substance, strengthened by eight bands of rather firmer texture, which are covered with rows of large vibratile *cilia*, ar-

ranged side by side, so as to form narrow plates of a fin-like character. There are, in the most common species, from three to seven *cilia* in each row, and about twenty rows on each ridge: over these the *Berœ* has complete control; it can retard or stop their movements at pleasure; and arrest the play of one, two, or more rows, whilst the remainder continue in rapid vibration, and act like so many little paddles. By these means it is capable of swimming through the water with considerable activity, and of changing its course at will. These little animals are of a bright faintly-blue aspect; and the *cilia* when in motion present vivid iridescent hues. The mouth is situated at one end, which is always directed forward when the animal is in motion, and is then widely dilated. From the stomach, there passes a narrow straight intestine, which terminates at the opposite extremity of the body. When the *Berœ* is in active movement, therefore, a continual stream of water will enter its mouth, and pass out again behind; and from the minute particles contained in the water, it evidently derives its nourishment; exceedingly minute crustacea may indeed be seen in the transparent stomach for some time after being swallowed. From the posterior part of the body arise two lengthened

BEROE.—(*CYDIPPE PILEUS*.)

filaments, or tentacula, furnished on one side with cirri, which are sometimes spread out as delicate hairs, and, at others, are spirally convoluted, or coiled like the tendrils of a pea. When the main filaments have been ejected from the body, the little tendrils begin to uncoil. If a *Berœ* is placed in a vessel of sea-water, its various movements may be watched with interest: sometimes it remains at the bottom, projecting its long filaments upwards; at others, it darts swiftly upwards, drawing its long filaments after it, and alternately retracting and extending them; not unfrequently it remains for some time at the top of the water, till at length, wishing to descend, it turns over, drawing up its filaments suddenly, and then swims, mouth-downwards, to the bottom.

In a small but interesting volume on the

Natural History of Arran by the Rev. David Landsborough, the author makes the following remarks on the species *Berœ cucumis*, several specimens of which he had taken during his "Excursions," to that island; the largest being three inches in length, by about one inch and a half in diameter. They varied, he says, from the size of a lemon to that of a lady's thimble, were very beautiful, and in shape resembling an antique pitcher contracted at the neck, with a graceful revolution, or turning back at the brim; but the exact form was difficult to assign, as it varied by partial contractions at the animal's pleasure. "The whole body has a tinge of pink, and the eight ribs closely set with cilia are beautifully adorned, having on each side an edging like fine crimson lace. In the larger specimens, this lace-work was studded with little orange oval-shaped bodies, like little grapes, attached by a capillary peduncle. When the *Berœ* was at rest, they rested; but when the cilia began rapidly to play, and the current of water, mixed at times with air-bubbles, to rush through the tubes of the ribs, then all the little orange bodies were in quick motion, as if dancing to the music of the spheres; or, believing in fairies as our forefathers did, one might have fancied that they were lace-bobbins, moved by nimble, invisible fairy hands, weaving the beautiful lace edging with which they were intermingled. Professor Forbes, however, says, as I had conjectured, that they are the eggs attached to the placental membranes; and I doubt not that they are thus shaken by the motion of the cilia, that when fully ripe they may thereby be detached."

Mr. Rymer Jones, in describing the beautiful mechanism of the *Berœ*, has made some pertinent philosophical reflections on it, in language at once elegant and forcible. "Man," says he, "justly prides himself, among the countless triumphs of his intellect over the stubborn elements, at his success in having found the means of struggling through the opposing surge, propelled by steam revolving wheels whose paddles urge his vessel on with giant force. But man in this contrivance, as in many more, is but a bungling artist when compared with Nature, when he chooses to adopt machinery which she likewise has employed. Examine well the *berœ*, and see if any paddle-wheels can equal hers. Stretching from pole to pole of this translucent little orb, like lines of longitude upon a globe, and placed at equal distances, are eight broad bands of more consistence than the other portions of the body. On these bands are placed thirty or forty paddles, broad flat plates, for such they seem when magnified, with which the little creature rows itself along. But here the difference lies between the art of Man and Nature. Man to move his wheels must have much cumbersome machinery; the furnace, and the boiler, and the Herculean arm that makes the wheel revolve; but here all these may be dispensed with, for the paddles are themselves alive, and move themselves at will with such degree of force as may be needed, either at once, or singly, or in groups, work-

ing with mutual consent in any way required. Thus do they all work equally; the *berœ* shoots along meteor-like, or, if a few relax their energy, wheels round in broad gyrations, or revolves on its own axis with an ease and grace inimitable."

BETTONGIA. A genus of Kangaroos, one of the species of which is called "Forest Rat" by the colonists of Van Diemen's Land (*B. cuniculus*): the end of the tail in this species has a white tuft. Another species (*B. fasciata*) was found by M. Peron on the west coast of Australia, at Dirk Hartog. It is very timid, and constructs galleries among the thick brushwood, by cutting away the lower branches and spines. It is of a brown colour, the lower part of the back being banded across with darker lines.

BIBIO: BIBIONIDÆ. A genus and sub-family of Dipterous insects, distinguished from all the other *Tipulidæ* by having the body and legs shorter and more robust; the antennæ cylindric, moniliform, or perfoliated; wings large; and the eyes of the males large and generally contiguous. There is great diversity in the sexes of the genus *Bibio*; all the species are of small size; and their flight is slow and heavy. They are found in damp, marshy places, flying in great swarms, and some of the species are amongst the most troublesome pests to our domestic animals.

BIMANA. [Two-handed.] The term applied by Cuvier to the first or highest order of Mammiferous Animals. It contains only one genus, and one species,—*MAN*; the sole created Being that can be termed truly *binanous* and truly *biped*. The whole body of Man is adapted for the vertical position: he walks erect; and thus preserves the entire use of his hands for the arts, while his organs of sense are most favourably situated for observation and the great mental purposes assigned to them by the Great Author of Nature. [See the articles *MAMMALIA* and *MAN*.]

BIPELTATA. A name given to those Crustacea which have the carapax divided into two shields, the anterior of which is very large, more or less oval, composing the head; and the second, corresponding with the thorax, is transverse and angulated in its outline, and bears the foot-jaws and the ordinary feet. The body is very flat, membranous, and transparent, with the abdomen small, and without spines to the posterior swimmeret. All the species are inhabitants of the Atlantic and Eastern Oceans.

BIPES. A genus of Reptiles in which the hind feet alone are visible, there being externally a total absence of the anterior extremities, though the rudiments of these members are perceptible under the skin. This genus affords an example of one of those beautiful gradations by which Nature glides from one type of form into another, being intermediate between the Saurians (*Lizards*) and the Ophidians (*serpents*).

BIRDS. In the following observations on the structure, habits, and uses of Birds, we

have endeavoured to collect, from the writings of various Ornithologists, such particulars as appeared to be best calculated to illustrate the subject in a manner the most simple, natural, and familiar; and in so doing we have made the just and sensible remarks of the ingenious Thomas Bewick the basis on which to build whatever we have thought necessary to add, or to glean from other sources.

Every part of nature is furnished with its proper inhabitants; the woods, the waters, and the depths of the earth, have their respective tenants; while the passive air and those tracts of seeming space too elevated for man to ascend, are traversed by multitudes of feathered beings, whose buoyancy and beauty are alike the objects of our admiration. But the symmetry and elegance discoverable in their outward appearance, although highly pleasing to the sight, are yet of much greater importance when considered with respect to their peculiar habits and mode of living, to which they are eminently subservient. Instead of the large head and formidable jaws, the deep capacious chest, the brawny shoulders, and the sinewy legs of the quadrupeds; we observe the pointed beak, the long and pliant neck, the gently swelling shoulder, the expansive wings, the tapering tail, the light and bony feet; which are all wisely calculated to assist and accelerate their motion through the yielding air. Every part of their frame is formed for lightness and buoyancy; their bodies are covered with a soft and delicate plumage, so disposed as to protect them from the intense cold of the atmosphere through which they pass; their wings are made of the lightest materials, and yet the force with which they strike the air is so great as to impel their bodies forward with astonishing rapidity, whilst the tail serves the purpose of a rudder to direct them to the different objects of their pursuit. The internal structure of birds is no less wisely adapted to the same purposes; all the bones are light and thin, and all the muscles, except those which are appropriated to the purpose of moving the wings, are extremely delicate and light; the lungs are placed close to the back-bone and ribs; the air entering into them by a communication from the wind-pipe, passes through, and is conveyed into a number of membranous cells which lie upon the sides of the pericardium, and communicate with those of the sternum. In some birds these cells are continued down the wings, and extended even to the pinions, thigh-bones, and other parts of the body, which can be filled and distended with air at the pleasure of the animal.

All birds are furnished with two very strong pectoral muscles on each side of their breast-bones. In quadrupeds, as well as in men, the pectoral muscles are trifling in comparison with those of birds. In the former, the muscles of the thighs and the hinder parts of the body are by far the strongest; but in birds it is far otherwise; the pectoral muscles which give motion to their wings are amazingly strong, whilst those of their thighs are weak and slender. By means of

these a bird can move its wings with a degree of strength which is almost incredible: the flap of a swan's wing would break the leg of a man; and a similar blow from an eagle has been known to cause instant death. Such, consequently, is the force of the wing, and such its lightness, as to be inimitable by human art.

The eyes of birds are admirably adapted to vision, by a particular expansion of their optic nerves, which renders the impression of external objects more vivid and distinct. From this peculiar conformation, it appears that the faculty of sight in birds is infinitely superior to that of other animals, and, indeed, is indispensably necessary to their support and security. Were the eye less perfect, the bird, from the rapidity of its motion, would probably strike against almost every object in its way; as well as be totally incapable of discerning its proper food when soaring in its own element.

In mental capacity birds fully equal quadrupeds, and in some respects surpass them. Parrots, starlings, &c., retain in memory many words and phrases which they have been taught, and many singing-birds whole melodies. Their powers of memory seem also to be evinced by the fact that birds of passage, after an absence of six months, or even a longer time, and after travelling thousands of miles, return to their former home; the swallow to her beam, the finch to the tree where last year she reared her young, or where she herself was hatched. The difference between such birds as love to dwell in uninhabited places, secure from persecution, and such as are found in the neighbourhood of men, surrounded by dangers, is a proof that their prudence, cunning, and docility can be awakened and improved.

The voice is a peculiar gift of Nature, by which the greater part of birds are distinguished from all the rest of the animal world. The wind-pipe of birds is composed of entire rings of cartilage, with an exception in the case of the ostrich. At its bifurcation is a glottis supplied with appropriate muscles, called the lower or inferior larynx. It is here that the voice of birds is formed; the vast body of air contained in the air-cells contributes to the force, and the wind-pipe, by its form and movements, to the modification, of the voice. The superior larynx is very simple and unimportant. The gift of song is given to the male birds only, and their notes are mostly an expression of love. They sing only when they are cheerful; in sadness, during rough weather, and in bodily disorders, they are silent. It is commonly said that the gift of song is confined to the birds in northern climates, and that nature, in the warmer regions, has endowed them, instead, with more brilliant colours; but Foster relates, that in Otaheite the birds sing with charming sweetness; and Cook, on his first voyage, found the forests of Queen Charlotte's Sound, in New Zealand, filled with little birds, whose voices sounded like silver bells. To no other animal have such various tones been granted for giving utterance to different feelings: hunger, fear,

the dread of imminent danger, desire for society, or longing for his mate, love, melancholy, &c., are expressed by a variety of notes, which make a language intelligible not only to birds of the same species, but often to the other tribes.

With respect to the feathers of birds, it has been truly said, that every form which the most sportive fancy could create out of the feathery material, and every hue that the warmest imagination could picture to itself, will be found among them. As a general rule, the plumage of the cock bird far exceeds in brilliancy that of the hen; and in many species a striking difference is observable between their plumage in summer and in winter; but in most birds two changes are observable; namely, that in the spring, which indicates the approach of the breeding season, when the bird obtains a certain portion of new feathers without losing any of the old ones; and in autumn, which is the moulting season, when the old feathers are thrown off, and new ones are produced in their places.

Birds may be distinguished, like quadrupeds, into two kinds or classes—granivorous and carnivorous; like quadrupeds too, there are some that hold a middle nature, and partake of both. Granivorous birds are furnished with larger intestines, and proportionally longer, than those of the carnivorous kind. Their food, which consists of grain of various sorts, is conveyed whole and entire into the first stomach or craw, where it undergoes a partial dilution by a liquor secreted from the glands and spread over its surface; it is then received into another species of stomach, where it is further diluted; after which it is transmitted into the gizzard or true stomach, consisting of two very strong muscles, covered externally with a tendinous substance, and lined with a thick membrane of prodigious power and strength: in this place the food is completely triturated and rendered fit for the operation of the gastric juices. The extraordinary powers of the gizzard in comminuting the food, so as to prepare it for digestion, would exceed all credibility, were they not supported by incontrovertible facts founded upon experiments. In order to ascertain the strength of these stomachs, the ingenious Spalanzani made the following among many other curious and interesting experiments:—He fixed twelve small lancets, very sharp, in a ball of lead, which was forced down the throat of a turkey-cock, and left eight hours in the stomach; at the expiration of which the organ was opened, but nothing appeared except the naked ball, the twelve lancets having been broken to pieces, the stomach remaining perfectly sound and entire. We may observe also, that stones taken into the stomach of birds are seldom known to pass with the feces, but being ground down and separated by the powerful action of the gizzard, are mixed with the food, and, no doubt, contribute essentially to the health of the animal.

Carnivorous Birds are distinguished by those endowments and powers with which they are furnished by nature for the purpose

of procuring their food: they are provided with wings of great length, the muscles which move them being proportionally large and strong, whereby they are enabled to keep long upon the wing in search of their prey: they are armed with strong hooked bills, and sharp and formidable claws; they have also large heads, short necks, strong and brawny thighs, and a sight so acute and piercing, as to enable them to view their prey from the greatest heights in the air, upon which they dart with inconceivable swiftness and undeviating aim. The analogy between the structure of rapacious birds and carnivorous quadrupeds is obvious; both of them are provided with weapons which indicate destruction and rapine; their manners are fierce and unsocial; and they seldom live together in flocks, like the inoffensive granivorous tribes. When not on the wing, rapacious birds retire to the tops of sequestered rocks, or to the depths of extensive forests, where they conceal themselves in sullen and gloomy solitude.

Without the means of conveying themselves with great swiftness from one place to another, birds could not easily subsist; the food which Nature has so bountifully provided for them is so irregularly distributed, that they are obliged to take long journeys to distant parts in order to gain the necessary supplies: at one time it is given in great abundance; at another it is administered with a very sparing hand; and this is one cause of those migrations so peculiar to the feathered tribes; the other chief causes are, the want of a proper temperature of air, and a convenient situation for the great work of breeding and rearing their young. Such birds as migrate to great distances are alone denominated "*birds of passage*;" but most birds are, in some measure, birds of passage, although they do not migrate to places very remote from their former habitations. At particular times of the year most birds remove from one country to another, or from the more inland districts towards the shores: the times of these migrations or flittings are observed with astonishing order and punctuality; but the secrecy of their departure, and the suddenness of their re-appearance, have involved the subject of migration in general in great difficulty. Much of this difficulty arises from our not being able to account for their means of subsistence during the long flights of many of those birds which are obliged to cross immense tracts of water before they arrive at the places of their destination: accustomed to measure distance by the speed of those animals with which we are well acquainted, we are apt to overlook the superior velocity with which birds are carried forward in the air, and the ease with which they continue their exertions for a much longer time than can be done by the strongest quadruped. On this part of the subject we have had occasion to make more particular observations, when speaking of the habits of certain migratory birds; we shall therefore merely add, from Bewick, that from the advantage they possess in being raised to considerable heights in the air, they are enabled, with a sagacity pecu-

liar to instinctive knowledge, to discover the route they are to take, from the appearance of the atmosphere, the clouds, the direction of the winds, and other causes; so that, without having recourse to improbable modes, it is easy to conceive, from the velocity of their speed alone, that most birds may transport themselves to countries lying at great distances, and across vast tracts of ocean.

At the approach of spring, birds begin to pair, and to provide for the support of their future progeny; and the loudest notes, on such occasions, generally proceed from the tuneful throats of the males, while the females express their consent in short interrupted twitterings. The compacts then entered into between the two sexes are, for the season at least, faithfully observed: but many birds live together for years with inviolable fidelity; and when one of them dies, the other does not long survive. We are of course not speaking of the poultry in our yards; but of those denizens of the air where Nature retains her unadulterated simplicity; where the number of males is generally equal to that of the females; and where every little animal seems no less pleased with its progeny than wedded to its mate.

The Nests of Birds now claim our notice; for they are constructed with such exquisite art, as to exceed the utmost exertion of human ingenuity to imitate them with perfect success. Their mode of building, the materials they make use of, as well as the situations they select, are as various as the different kinds of birds, and are all admirably adapted to their several wants and necessities. Birds of the same species, whatever region of the globe they inhabit, collect the same kind of materials, arrange them in the same manner, and make choice of similar situations for fixing the places of their temporary abodes. Every part of the world furnishes materials for the aerial architects: leaves and small twigs, roots and dried grass mixed with clay, serve for the external; whilst moss, wool, fine hair, and the softest animal and vegetable downs, form the warm internal part of these commodious dwellings. On this subject the author of "The Journal of a Naturalist" thus writes: Birds that build early in the spring seem to require warmth and shelter for their young; and the Blackbird and the Thrush line their nests with a plaster of loam, perfectly excluding, by these cottage-like walls, the keen icy gales of our opening year: yet, should accident bereave the parents of their first hopes, they will construct another, even when summer is far advanced, upon the model of their first erection, and with the precautions against severe weather, when all necessity for such provision has ceased, and the usual temperature of the season rather requires coolness and a free circulation of air. The House-sparrow will commonly build four or five times in the year, and in a variety of situations, under the warm eaves of our houses and our sheds, the branch of the clustered fir, or the thick tall hedge that bounds our garden, &c.: in all which places,

and without the least consideration of site or season, it will collect a great mass of straw and hay, and gather a profusion of feathers from the poultry-yard to line its nest. This cradle for its young, whether under our tiles in March or in July, when the parent bird is panting in the common heat of the atmosphere, has the same provisions made to afford warmth to the brood; yet this is a bird that is little affected by any of the extremes of our climate. The Wood-pigeon and the Jay, though they erect their fabrics in the tall underwood in the open air, will construct them so slightly, and with such a scanty provision of materials, that they seem scarcely adequate to support their broods, and even their eggs may almost be seen through the loosely-connected materials: but the Goldfinch, that inimitable spinner, the Arachne of the grove, forms its cradle of fine mosses and lichens, collected from the apple or the pear-tree, compact as a felt, lining it with the down of thistles besides, till it is as warm as any texture of the kind can be, and it becomes a model for beautiful construction. The golden-crested Wren, a minute creature, perfectly unmindful of any severity in our winter, and which hatches its young in June, the warmer portion of our year, yet builds its most beautiful nest with the utmost attention to warmth; and, interweaving small branches of moss with the web of the spider, forms a closely-compacted texture nearly an inch in thickness, lining it with such a profusion of feathers, that sinking deep into this downy accumulation it seems almost lost itself when sitting, and the young, when hatched, appear stifled with the warmth of their bedding and the heat of their apartment; while the White-throat, the Black-cap, and others, which will hatch their young nearly at the same period, or in July, will require nothing of the kind. A few loose bents and goose-grass, rudely entwined, with perhaps the luxury of some scattered hairs, are perfectly sufficient for all the wants of these; yet they are birds that live only in genial temperatures, feel nothing of the icy gales that are natural to our pretty indigenous artists, but sit from sun to sun, and we might suppose would require much warmth in our climate during the season of incubation; but it is not so. The Greenfinch places its nest with little regard to concealment; its fabric is slovenly and rude, and the materials of the coarsest kinds; while the Chaffinch, just above it in the elm, hides its nest with cautious care, and moulds it with the utmost attention to order, neatness, and form. One bird must have a hole in the ground; to another, a crevice in a wall, or a chink in a tree, is indispensable. The Bullfinch requires fine roots for its nest; the grey Flycatcher will have cobwebs for the outworks of its shed. All the *parus* tribe, except the individual above mentioned, select some hollow in a tree or cranny in a wall; and, sheltered as such places must be, yet will they collect abundance of feathers and warm materials for their infants' bed. Endless examples might be found of the dissimilarity

of requirements in these constructions among the several associates of our groves, our hedges and our houses; and yet the supposition cannot be entertained for a moment that they are superfluous, or not essential for some purpose with which we are unacquainted. By how many of the ordinations of Supreme Intelligence is our ignorance made manifest! Even the fabrication of the nests of these little animals exceeds our comprehension—we know none of the causes or motives of that embodied mind that willed them thus."

The difference of climate sometimes occasions vast alterations in the construction of the nests of birds. Some water-fowl strip the down from their own breasts, for the purpose of lining their nests with greater security. In general, however, all birds, when hatching, resort to those climates and places where their food is found in the greatest plenty. Aquatic birds, as well as the largest of the land kinds, select such situations as are most remote from man; their food, in general, being different from that which is cultivated by human labour. Some birds, which regard the serpent as their deadliest foe, build their nests depending from small boughs, and form their entrances from below; thereby equally securing them from the serpent and the monkey tribes; but small birds, which feed upon fruits and corn, make use of every precaution to conceal their nests from man; while the great birds, remote from human society, employ every art to render theirs inaccessible to wild beasts and vermin.

While the female is hatching, nothing can exceed her patience; neither the calls of hunger, nor the near approach of danger, being capable of driving her from her nest. Though fat when she begins to sit, before the time of incubation is expired she is usually reduced to little more than skin and bone. While the young continue in the nest, the old ones provide them with a proper supply of food; and, that no individual may be overlooked, each is served in its turn. If they perceive that man has been busy with their nest, or has handled their little ones, they abandon the place by night, and provide their brood a more secure retreat. When the whole family are fully plumed, and capable of avoiding danger, they are led forth in fine weather, and taught the art not only of providing for their own subsistence, by being conducted to those places where their food is most likely to be found, but of picking it up and carrying it away. After the business of incubation is entirely over, and the young are sufficiently able to provide for themselves, the nests are abandoned by the parents, except by those of the eagle kind.

Most of the smaller birds are supported, especially when young, by a profusion of caterpillars, small worms, and insects; on these they feed, and thus they contribute to preserve the vegetable world from destruction. This is contrary to the commonly-received opinion, that birds, particularly Sparrows, do much mischief in destroying the labours of the gardener and the husband-

man. It has been observed, "that a single pair of Sparrows, during the time they are feeding their young, will destroy about four thousand caterpillars weekly; they likewise feed their young with butterflies and other winged insects, each of which, if not destroyed in this manner, would be productive of many thousands of caterpillars." Swallows are almost continually upon the wing, and in their curious winding flights destroy immense numbers of flies and other insects, which are continually floating in the air, and which, if not destroyed by these birds, would render it unfit for the purposes of life and health. That active little bird, the Tom-tit, which is generally supposed hostile to the young and tender buds that appear in the spring, when attentively observed, may be seen running up and down among the branches, and picking up the eggs of insects, or the small maggots or worms that are concealed in the blossoms, and which would effectually destroy the fruit. As the season advances, various other small birds, such as the Redbreast, Wren, Hedge-warbler, White-throat, Redstart, &c., are all engaged in the same useful work, and may be observed examining every leaf, and feeding upon the insects which they find beneath them. These are a few instances of that superintending providential care which is continually exerted in preserving the various ranks and orders of beings in the scale of Animated Nature; and although it is permitted that myriads of individuals should every moment be destroyed, not a single species is lost, but every link of the great chain remains unbroken.

The only disease, if it can be termed one, to which birds are subject, is moulting, or the operation of changing their plumage, during the continuance of which they are sickly and disordered, and many die. This process, which occurs every year, appears to be performed in the following manner:—When the feathers have attained their full size, the quill part, nearest the bird, grows harder, and shrinks in its diameter, thus gradually compressing, and finally obliterating the vessels which supply it with nourishment, and thus becomes an extraneous body which is at last loosened in its socket, and falls off. Whilst these changes are taking place, the rudiments of the new feather are forming beneath, which rapidly attains its natural size, after it has been protruded through the skin, a process which, it will be seen, is very analogous to the annual shedding of the horns in the deer tribe.

Although some birds, by emigrating, make their habitations in different parts of the earth, almost every climate has such as are peculiar to it. Those of the temperate zone are not very remarkable for the beauty of their plumage; but the smaller kinds fully compensate this defect by their melodious notes. Many birds of the torrid zone are resplendent in beauty, but in general they have either harsh and disagreeable voices, or are totally silent: the frigid zone, on the contrary, where the adjacent seas abound with fish, is stocked with birds of the aquatic kind, in much greater plenty than in Eu-

rope; and these are generally either clothed with warm coats of feathers, or have large quantities of fat lying beneath the skin, to defend them from the rigours of the climate. In all climates, however, birds are longer lived than quadrupeds of the same climates: indeed, it may be said, that, in proportion to the size of their bodies, birds possess more vitality, and live longer, than either man or quadrupeds.

Naturalists have arranged birds in various orders, founded on the organs of manducation and prehension. The following is that of Cuvier:—1. *BIRDS OF PREY* (*Accipitres*, Lin.); distinguished by their crooked beak and claws, by means of which they are enabled to overcome and prey upon other birds, and even the weaker quadrupeds. They hold the same rank among birds as the *Carnivora* among quadrupeds. They all have four toes, and the nails of the great and middle toes are the strongest. They form two families, the *diurnal* and *nocturnal*, the first having nostrils inserted in a naked cere, three toes before and one behind, without feathers; eyes directed sideways: the second having nostrils at the anterior edge of the cere, which is more or less covered with stiff hairs; the external toe capable of being turned behind; eyes large, directed forwards.—2. *PASSERINE BIRDS* (*Passeres*). This is the largest class, and embraces all birds which do not belong to the other five. They present a great resemblance in their structure, and the genera are so closely allied that it is difficult to distinguish between them. They may, however, be separated into two great divisions: 1. Those with the exterior toe united to the middle one, by one or two joints only; and, 2. Exterior toe almost as long as the middle one, and united to it as far as the last joint but one.—3. *CLIMBERS* (*Scansores*). Birds whose exterior toe directs itself backwards like the great toe, affording a very solid support, by which some of them cling to and climb the trunks of trees.—4. *GALLINACEOUS BIRDS*. (*Gallinaceæ*.) These have a heavy gait, a short flight, a medium-sized beak, the upper mandible vaulted, nostrils partly covered by a cartilaginous scale, toes generally dentated at the edges, with short membranes between those in front.—5. *WADERS* (*Grallæ*) may be recognised by the nudity of the lower part of their thighs; very frequently by the length of their legs; and generally by some little web, at least, between the external toes. In flying, they extend their legs behind them, contrary to the habit of other birds, who draw them up close to the body.—6. *WEB-FOOTED BIRDS* (*Palmipedes*) are strongly characterised by their feet, formed for swimming, being affixed to the hinder part of their body; with very short and compressed tarsi; and palmated between the toes.—For much information on the habits of Birds we would refer to the pages of Loudon's Magazine of Natural History, and to "The Zoologist;" while the great work, "Gray and Mitchell's Genera of Birds," contains an immense supply of matter in illustration of this important and interesting class. In Macgillivray's "British Birds" much valu-

able information is given by the able professor of Marischal College, Aberdeen.

BIRGUS. A genus of long-tailed Crustaceous animals, of which the *PURSE-CRAB* (*Birgus latro*) is the largest. This species of land-crab is a native of Amboyna, and other neighbouring islands, where it is said to inhabit the fissures of rocks or holes in the earth by day, and to come forth at night to seek its food on the beach. Some say it climbs cocoa-nut trees in the night to get the cocoa-nuts; and it is certain it can subsist on them, as well as on some other kinds of nuts, when more favourite food is not easily attainable. When properly dressed, this animal is regarded as an excellent dish. [See CRAB.]

BISON. There are two kinds of Bison; one of them European, which is now become very scarce; the other American, which still exists in vast numbers.

The **EUROPEAN BISON** (*Bos bonasus*) is as large as a bull or ox; and in his native state of wildness, is distinguished not only by his size and the fleshy protuberance on his shoulders, but by the superior depth and shaginess of his hair, which about the head, neck, and shoulders, is sometimes so long as almost to touch the ground. The head is small; the eyes are red and fiery; the forehead is wide; and the horns are short, extremely strong, sharp-pointed, and stand distant from each other at their bases, like those of the common bull. His colour is a dark rufous brown, sometimes nearly black; his limbs remarkably strong; and his whole aspect in the highest degree savage and gloomy. The principal European regions where this animal is at present found, are the marshy forests of Poland, the Carpathian mountains, and Lithuania. Its chief Asiatic residence is the neighbourhood of Mount Caucasus. This animal is very scarce, and would probably soon be extinct but for the strict orders of the emperor of Russia, who will not permit any to be shot in his dominions. This monarch has presented a stuffed specimen and skeleton of one to the British Museum.

The **AMERICAN BISON**. (*Bos Americanus*.) The American Bison, most frequently called "the Buffalo," differs from the European chiefly in being larger, more shaggy, in having a more protuberant bunch over the shoulders, and by the length and fineness of its woolly hair. The hump is oblong, diminishing in height posteriorly, and gives a considerable obliquity to the outline of the back. The hair over the head, neck, and fore-part of the body is long and shaggy, forming a beard beneath the lower jaw, and descending below the knee in a tuft. The hair on the top of the head rises in a dense mass, nearly to the tips of the horns, and, directly on the front, is curled and matted strongly. The numbers of this species still existing are surprisingly great, when we consider the immense destruction which annually takes place. They were once extensively diffused over the whole of the territory of the United States, but they are no longer found except in the

BISON OR, BUFFALO.—(BOS AMERICANUS.)

remote unsettled regions of the north and west, being rarely seen east of the Mississippi or south of the St. Lawrence.

The Bison, on his native plains, is of a savage and formidable appearance; nevertheless, he is not known to attack man, unless when wounded and at bay. The difference between the summer and winter dress of the Bison consists rather in the length than in other qualities of the hair. In summer, from the shoulders backwards the surface is covered with a very short, fine hair, smooth and soft as velvet. The tail is short, and tufted at the end; and the general colour of the animal is a uniform dun. Varieties of colour are, indeed, so rare among the species, that the hunters and Indians always regard them as matters of special wonder. Herds, consisting of thousands of these fine animals, still roam over the far western prairies, led by the fiercest and most powerful of the bulls. During the sexual season the noise of their roaring is terrific, and the males often fight with all the fury of desperation. While feeding, they are frequently scattered over a vast surface; but when they move onward in a mass, they form a dense, impenetrable column, which, once fairly in motion, is scarcely to be turned. They swim larger rivers in nearly the same order in which they traverse the plains; and, when flying from pursuit, it is in vain for those in front to halt suddenly, as the rearward throng dash madly forward, and force their leaders on. The Indians sometimes profit by this habit; they lure a herd to the vicinity of a precipice, and, setting the whole in rapid motion, they terrify them, by shouting and other artifices, to rush on to their inevitable destruction.

There are various modes of capturing or killing these animals; but there are none which require so much dexterity as the hunting them on horseback; which is thus described by Sir John Franklin:—"An expert hunter, when well mounted, dashes at the herd, and chooses an individual which he endeavours to separate from the rest. If he succeeds, he contrives to keep him apart by the proper management of his horse, though going at full speed. Whenever he can get sufficiently near for a ball to penetrate the beast's hide, he fires, and seldom fails of bringing the animal down; though of course he cannot rest the piece against the shoulder,

nor take deliberate aim. On this service the hunter is often exposed to considerable danger from the fall of his horse in the numerous holes which the badgers make in these plains, and also from the rage of the buffalo (Bison), which, when closely pursued, often turns suddenly, and, rushing furiously on the horse, frequently succeeds in wounding it, or dismounting the rider." "When the buffaloes are on their guard, horses cannot be used in approaching them; but the hunter dismounts at some distance and crawls in the snow towards the herd, pushing his gun before him. If the buffaloes happen to look towards him he stops, and keeps quite motionless, until their eyes are turned in another direction; by this cautious proceeding a skilful person will be able to get so near as to be able to kill two or three out of the herd." When wounded they are very furious; their hoofs, more than their horns, are their offensive weapons, and whatever opposes them is in no small danger of being trampled into the earth.

The Hon. C. A. Murray, in his Travels in North America, where he had excellent opportunities of studying the habits of this animal in his native haunts, tells us that, "The Buffalo, huge and unwieldy as he is, goes over the ground at a rate which is surprising; he bounds along with large, though clumsy strides; and in a rough country he dashes down the steep sides of the broken ravines, making the dust, the sand, and the stones fly around with a furious rapidity, that defies the pursuit of a rider who has any regard for the neck of his horse or himself. The female, the constant object of the hunter, from the superior quality and tenderness of her flesh, is beyond all comparison swifter than the male; she can run nearly three miles to his two, and gives a very fair chase to a horse of middling speed, fed only on grass, and carrying a man of only ordinary size."

Numerous tribes of Indians are almost wholly dependent on these animals for food, tents, clothing, utensils, &c. The skins, dressed in the Indian fashion, with the hair on, make admirable defences against the cold, and may be used for blankets, &c. They are called *buffalo robes*; the term *Buffalo* being generally, but inaccurately, applied to the Bison. The horns of the Bison are converted into powder-flasks; while their wool has been manufactured into hats, and has also been employed in making coarse cloth. Bison beef is rather coarser grained than that of the domestic ox, but is considered by hunters and travellers as superior in tenderness and flavour. The hump, which is highly celebrated for its richness and delicacy, is said, when properly cooked, to resemble marrow. The Hon. Mr. Murray, in the work from which we have already quoted, says, "I cannot convey any just impression of the total dependence of the remote western tribes on Buffalo for their very existence, without giving a sketch of the various purposes for which that animal is, by their ingenuity, rendered available. First, its flesh is their principal, sometimes their only food; eaten fresh on the prairies during

their hunt, and dried in their winter villages. Secondly, the skin is put to various uses; it forms the material of their lodges, of their bales for packing the meat, of their bed by night, and their clothing by day; the coarser parts they make into saddles, or cut into laryettes, or halters; and, more than all, it is now their chief article of trade with the whites, and thus is the source whence they must derive blankets, knives, beads, and every other produce of civilization. Thirdly, they use the sinews as strings to their bows, and the smaller fibres instead of twine or thread; the brains serve to soften and dress the skins, while the hoof, at the end of the shank bone, is made to answer the purpose of a mallet. Fourthly, the bones are not less useful: some of them being serviceable as scrapers or close chisels; others are pointed, and used with the finer fibres as needle and thread; and the ribs, strengthened by some of the stronger fibres, are made to furnish the bow with which other Buffaloes are to be destroyed. This last is the triumph of Indian ingenuity. The first bow that I saw constructed in this manner caused so much surprise and admiration, that I offered nearly the value of a horse for it, but was refused. When I add to the foregoing particulars, that on the barren prairies the Indians frequently depend upon the Buffalo (dung) for their fuel, and on its bladder for the means of carrying water, it will not be denied that the animal is essential to their existence; and when the Buffalo is exterminated, the Indian of the Prairies must perish."—For further particulars we must refer our readers to the delightful pages of Sir John Richardson, M. D. (*Fauna Boreali Americana*), and of Mr. Catlin.

BITTERN. (*Botaurus.*) The Bitterns are a subgenus of the family of Herons, residing in woody swamps and marshy places, and feeding upon aquatic animals, frogs, lizards, insects, &c. The COMMON BITTERN (*Botaurus stellaris*) is about two feet six inches in length, or nearly as large as the common heron, but its legs are stronger; body more plump and fleshy; and its neck is more thickly clothed with feathers. The beak is strong at the base, straight, sharp on the edges, and gradually tapers to an acute point; the upper mandible is brown, the under inclining to green; mouth wide, the gape extending beyond the eyes, with a dusky patch at each angle: irides yellow. The crown of the head is somewhat depressed, and covered with long black feathers; and the neck feathers, which it can raise at pleasure, are long and loose. The general colour of the plumage is dull pale yellow; the back and wings are marked with black zig-zag lines, bars, and streaks, upon a ground shaded with rufous and yellow; and the greater coverts and quills are regularly barred with black. The tail is very short; the legs are pale green; the toes and claws very long and slender. The female is somewhat smaller than the male, the plumage not quite so bright, and the feathers on the neck shorter. She makes an artless nest, composed chiefly of the withered stalks and leaves of the high

coarse herbage, in the midst of which it is placed, and lays from four to six eggs of a greenish white.

The Bittern is a shy solitary bird; it is never seen on the wing in the day-time; but sits generally with the head erect, hid among the reeds and rushes of extensive marshes, from whence it will not stir unless disturbed by the sportsman. When it changes its haunts, it removes in the dusk of the evening, and then, rising in a spiral direction, soars to a vast height. It flies in the same heavy manner as the heron, and might be mistaken for that bird, were it not for the singularly resounding cry which it utters from time to time, while on the wing; but this cry is feeble when compared with the hollow booming noise which it makes during the night, in the breeding season, from its swampy retreats. From the loudness and solemnity of its note, an erroneous notion prevails with the vulgar that it either thrusts its bill into a reed, which serves as a pipe for swelling its note beyond its natural pitch, or that it immerses its head in water, and then produces its boomings by blowing with all its might.

When attacked by the buzzard, or other bird of prey, the Bittern defends itself with great courage, and generally beats off such assailants; neither does it betray any symptoms of fear when wounded by the sportsman, but eyes him with a keen undaunted look, and, when driven to extremity, will attack him with the utmost vigour, wounding his legs, or aiming at his eyes with its sharp and piercing bill. Bitterns reside permanently in England, and in most of the temperate parts of the continent; but in colder climates they are migratory. They were formerly held in great esteem at the tables of the wealthy.

There are several other species of this bird, some of them natives of hot and others of cold climates; but they all resemble the above in its distinguishing characteristics, frequenting the same situations, making their nests on the ground, &c., but differing materially in the colours of their plumage as well as in size.

BIVALVE. The name given to a class of shells composed of two pieces or parts; which, by means of a proper connection by hinges, open and shut, and perform all other functions necessary to the economy or modes of life of the animals included in them. The Mollusca inhabiting them are chiefly distinguished from the other classes by the absence of a visible head or neck, and the consequent deprivation of the organs of sight and hearing: they possess a mouth, but it is a mere opening in the body, with jaws or teeth. The branchiæ are large, placed on each side, between the body and the mantle. The lobes of the mantle are fringed round the edge with numerous filaments, which are very sensitive, and in constant activity. None of the genera are terrestrial, their construction not affording them sufficient powers of locomotion for finding their food on land, and confining them to the water, whether salt or fresh, or to the sands on the coasts. As

familiar instances we may mention the Oyster, Mussel, Cockle, &c.

BIZCACHA, or VIZCACHA. (*Calomys bizcacha*.) A Rodent animal, somewhat resembling a rabbit, but with larger gnawing teeth and a long tail: it has, however, only three toes behind, like the Agouti. Near Buenos Ayres they are exceedingly common. They are said to live on roots; which, from the great strength of their gnawing teeth, and the kind of localities they frequent, seems probable. As in the case of the rabbit, a few holes are commonly placed together. In the evening the Bizcachas come out in numbers, and there quietly sit on their haunches. They do not wander far from their burrows: they run very awkwardly, and, when hurrying out of danger, from their elevated tails and short front legs, much resemble great rats. Their flesh, when cooked, is very white and good, but it is seldom used. Of late years the skins of the Bizcacha have found a market in England, on account of the fur.

BLACKBIRD. (*Turdus merula*.) A well-known song-bird, about ten inches long, whose deep-toned warblings are not to be mistaken for those of any other inhabitant of the groves. The plumage of the male bird is altogether black, but that of the female is rather of a brown or dark russet colour: the bill, inside of the mouth, and edges of the eyelids, are yellow, as are also

BLACKBIRD.—(*TURDUS MERULA*.)

the soles of the feet. The males during the first year resemble the females so much as not easily to be distinguished from them; but after that, they assume the yellow bill and other distinguishing marks of the sex. The Blackbird is a solitary bird, frequenting woods and thickets, chiefly evergreens, especially where there are perennial springs, which together afford it both shelter and subsistence. They feed on berries, fruit, insects, and worms; but never fly in flocks like thrushes. They pair early, and are among the first who render the groves vocal: the note of the Blackbird, indeed, during the spring and summer, when heard at a distance, is rich and enlivening; but when the bird is confined in a cage, its song is too loud and deafening. They build in bushes or low trees, and lay four or five eggs, of a bluish-green, marked irregularly with dusky spots. The young birds are easily tamed, and may be taught to whistle a variety of tunes. They are restless and timorous, easily alarmed, and difficult of access. We

occasionally hear of *albino*s, or white black-birds; but they are so rare as to be regarded in the light of great curiosities.

BLACK-CAP. (*Sylvia atricapilla*.) This is a small song-bird, whose notes are so sweet and full that it has obtained the name of the mock-nightingale. The crown of the head, in the male, is black; the hind part of the neck, light ash colour; back and wings, olive grey; throat, breast, and belly, more or less silvery white; legs bluish, and claws black. The Black-cap is migratory, visiting us about the middle of April, and retiring in September. Orchards and gardens are its favourite haunts; and it builds its slightly constructed nest in some low tree or shrub,

BLACK-CAP.—(*SYLVIA ATRICAPILLA*.)

lining it with the fibres of roots thinly covered with horse hairs: the eggs are reddish brown mottled with a deeper colour, and sprinkled with dark spots. The Black-cap is naturally a very shy bird; and although while banqueting on currants, raspberries, or any of its favourite fruits, it seems to forget its usual timidity, and suffers itself to be looked at, yet at other times it avoids observation as much as possible, and carefully hides itself in the foliage from all familiarity and confidence. Its song, however, never fails to attract attention; for although its modulations are in general short and desultory, yet when this little warbler sits calmly, and is earnestly engaged in singing, it gives utterance to a pleasant and gentle harmony, superior perhaps to any of our other songsters, the nightingale excepted.

BLACK-COCK, and BLACK-GAME. [See GROUSE.]

BLAPS: BLAPSIDE. A genus and family of Coleopterous insects; the type of which is the species *Blaps mortisaga*: it is black, but little shining, and the tip of the elytra forms a short obtuse point. It is a very common British insect, found in dark, damp, and dirty places about houses. In Mr Westwood's "Introduction to the Modern Classification of Insects," the following extraordinary fact is related:—Several instances have been noticed, in which the larvæ of the common species *Blaps mortisaga*, or Church-yard Beetle, has been discharged from the stomach. Of these, the most remarkable account is that published by Dr. Pickell in the *Trans. of Associated*

HURCH-YARD BEETLE.
(*BLATTA MORTUARIA*.)

Physicians in Ireland, of a case of a woman, aged twenty-eight, who emitted as many as two thousand larvæ of this insect at various times, as well as one pupa and one imago; and which probably originated in an absurd and superstitious practice, which she had for some time followed, of drinking daily for a certain time a quantity of water mixed with clay, taken from the graves of two Catholic priests, and eating large pieces of chalk. One of these beetles was immersed repeatedly into spirits of wine, but revived after remaining therein all night, and afterwards lived three years."

* **BLATTIDÆ.** A family of voracious insects, of the order *Orthoptera*, of which the troublesome Cockroach (*Blatta orientalis*) is a well-known example. These very destructive and disagreeable insects form one of the principal inconveniences of hot climates. They devour various animal and vegetable substances; and some species have a highly unpleasant smell, which is apt to remain on such articles as they have passed over. The largest of the genus is the

BLATTA GIGANTEA of Linnaeus, which is a native of many of the warmer parts of Asia, Africa, and South America. The following description of them is said, by those who have visited the countries where they abound, to be by no means overcharged: "They plunder and erode all kinds of victuals, drest and undrest, and damage all sorts of clothes, especially such as are touched with powder, pomatum, and similar substances; everything made of leather, books, paper, and various other articles, which if they do not destroy, at least they soil, as they frequently deposit a drop of their excrement where they settle, and some way or other by that means damage what they cannot devour. They fly into the flame of candles, and sometimes into the dishes; are very fond of ink and of oil, into which they are apt to fall and perish; in which case they soon turn most offensively putrid: so that a man might as well sit over the cadaverous body of a large animal as write with the ink in which they have died. They often fly into persons' faces or bosoms, and their legs being armed with sharp spines, the pricking excites a sudden horror not easily described. In old houses they swarm by myriads, making every part filthy beyond description wherever they harbour, which in

the day-time is in dark corners, behind clothes, in trunks, boxes, and, in short, every place where they can lie concealed. In old timber and deal houses, when the family is retired at night to sleep, this insect, among other disagreeable properties, has the power of making a noise which very much resembles a pretty smart knocking with the knuckle upon the wainscoting. The *Blatta Gigantea*, in the West Indies, is therefore frequently known by the name of the *drummer*. Three or four of these noisy creatures will sometimes be impelled to answer one another, and cause such a drumming noise that none but those who are very good sleepers can rest for them. What is most disagreeable, those who have not gauze curtains are sometimes attacked by them in their sleep: the sick and dying have their extremities attacked, and the ends of the toes and fingers of the dead are frequently stripped both of the skin and flesh."

The **BLATTA ORIENTALIS**, or common black Cockroach, which is frequently called in our country by the erroneous name of the *black beetle*, is supposed to have come originally from Asia; but of that there is some little doubt. In its mature state the male has wings extending only half the length of the body; the female has only rudimentary wings; her eggs, which are about sixteen in number, are enclosed in an oblong case, which she carries about with her at first, fixed to the abdomen by a sort of gum. The nocturnal habits and ravages of this species are too well known to require any description.

The **BLATTA AMERICANA**, or American Cockroach, is of a light chestnut or reddish colour, and is extremely common in the warmer parts of America and the West India islands. It is somewhat larger than the black or eastern Cockroach. These *Blattæ* lay their eggs in heaps, and wrap them all round in webs or bags, after the manner of some spiders. When the eggs are hatched, the young ones appear quite perfect, and leave their shells almost instantaneously. Being at first no larger than ants, they are capable of penetrating through the smallest apertures into boxes and chests, where they destroy everything within their reach. When arrived at their full growth, they cast their skins, which burst on their backs; and then the *Blattæ*, or Cockroaches, are perfectly formed: their wings are at first soft and whitish, and they soon become red; but their heads, horns, and the rest of their bodies, retain the same shapes and colours as they possessed before the exuvium were shed.

BLEAK. (*Cyprinus alburnus*.) This Malacopterygious fish belongs to the Carp family, and is very common in many of our own rivers: the length about five or six inches; shape slender, with the body much compressed; colour bright silvery, the back olive-green; fins pellucid; scales deciduous; and the tail forked. Bleaks generally keep together in large shoals; and at certain seasons they are observed to tumble about near the surface of the water as if incapable of swimming to

RYFAK.—(GYPRINUS ALBURNUS.)

any considerable distance; but in a short time they recover, and presently disappear. It is from the scales of this fish that the beautiful silvery matter used in the preparation of artificial pearls is chiefly taken; other bright-scaled fishes may, however, be used for the same purpose.

BLENNY. (*Blennius*.) A genus of small Acanthopterygious fishes, living in small shoals, and frequenting rocky coasts, where they may be often found in pools of water left by the tide. The Bleunies have one well-marked character in their ventral fins, inserted before the pectorals, and having only two rays each. The stomach is slender, with no cul-de-sac; the intestine large, without cæca, and there is no air-bladder. The form is elongated and compressed, and there is but one dorsal, composed almost entirely of jointless but flexible rays. Their skin is covered with a mucous secretion; they have teeth equal and closely set, forming only a single row in each jaw; their head is blunt, their profile vertical, and their muzzle short. There are several species; a brief description of three, however, will be ample.

The **CRESTED BLENNY.** (*Blennius gasterita*.) This species is about four or five inches in length, and is found about the rocky coasts of Great Britain. The body is long, compressed, smooth, and slippery; colour yellowish brown, freckled with darker coloured specks; head furnished on the middle with a transverse finny appendage, which can be either raised or depressed at pleasure; and between the eyes is a small triangular prominence, pointing backward, and red about the edges; ventral fins very small and short, dorsal shallow, running from the hind part of the head to the tail, which is of a round shape, and the vent situated under the ends of the pectoral fins.

The **OCELLATED BLENNY,** or **BUTTERFLY FISH.** (*Blennius ocellaris*.) This very small species is a native of the Medi-

OCELLATED BLENNY, OR BUTTERFLY-FISH
(*BLENNIUS OCELLARIS*.)

terranean, but is occasionally found in the South of England by dredging. It has two lobes in the dorsal, the first marked with a

round black spot surrounded by a white ring, and then a black one. It lives among the rocks and sea-weed, and is believed to subsist on minute Crustacea and Mollusca.

The **GATTORUGINOUS BLENNY** (*Blennius Gattorugin*) is about six inches long; the body smooth, and compressed on the sides; the belly rather prominent, and the vent situated as in the crested Blenny. The head is grooved between the eyes, and furnished with two branched membranes, situated just above the eyelids, a distinguishing mark of the species. The pectoral fins, which are broad and rounded, consist of fourteen rays; the dorsal fin has thirty-three; the ventral two; the anal twenty-three; and the tail, which is slightly rounded, has eleven rays. This fish is of a dusky colour, marked across with wavy lines. It has occasionally been found on our western coasts, but is not very common.

BLEPHARIS. A genus of Acanthopterygious fishes, distinguished by their having long filaments to their second dorsal and to their anal fin rays. One species of the *Blepharis*, inhabiting the West Indian seas, is known under the appellation of the *Cobler-fish*, probably on account of the long thread-like appendages for which it is so conspicuous.

BLEPSIAS. A genus of Acanthopterygious fishes, the generic characters of which are,—compressed head, cheeks mailed, fleshy barbels under the lower jaw, gills with five rays, and one dorsal fin divided into three unequal lobes.

BLETHISA. A genus of carabidous Coleopterous insects, consisting of three known species, only one of which has been found in this country: this is about half an inch long, of a rich bronze or brassy hue, and with numerous indented points on the elytra: it frequents marshy situations, and is often found crawling upon willow trees.

BLIND-WORM, or **SLOW-WORM.** (*Anguis fragilis*.) A species of viviparous reptile belonging to the third subgenus of the family *Anguidae*, which may be said to form the connecting link between the lizards and the true serpents. Though somewhat formidable in appearance, the Blind-worm is perfectly innocuous. Its usual length is about eleven inches; the head is small; the eyes are also small, and the irides red; the neck is slender, and thence the body enlarges, continuing of equal bulk to the tip of the tail, which ends bluntly, and is as long as the body. The general colour of the back is cinereous, marked with very small lines of minute black specks; the scales are small, smooth, and shining, of a silvery yellow on the upper parts, and dusky beneath; the tongue is broad and forked; and the teeth are very small and numerous. The Blind-worm feeds on earthworms, insects, &c., and among the uninformed has the character of possessing the most deadly venom. The motion of this reptile is slow; from which circumstance, as well as from the smallness of its eyes, its names are derived. Like all

the rest of the kind, in our climate, they lie torpid during the winter, being sometimes found in vast numbers twisted together.

BLOODHOUND. (*Canis [domesticus] sanguinarius.*) A well-marked variety of dog, celebrated for its exquisite scent and unwearied perseverance, qualities which were highly esteemed by our ancestors for tracing and recovering such game as had escaped from the hunters in a wounded state, or had been killed and stolen out of the royal forests. These hounds were also formerly much employed in pursuing criminals escaped from justice, or in tracing out robbers or enemies, whose course was inevitably discovered when once the Bloodhound was placed upon their trail. The genuine Bloodhound breed was large, strong,

BLOODHOUND
(*CANIS [DOMESTICUS] SANGUINARIUS.*)

muscular, broad-chested, the upper lip large and pendulous; the expression stern and noble; the colour a deep tan, and generally marked with a black spot over each eye; this species, however, seems now to be blended with the other smaller hounds, and the original stock is all but extinct.

Sir Walter Scott and other writers narrate many surprising feats of the "scent-hound," whose unflinching pertinacity generally overcame all impediments, whether engaged in the usual objects of the chase, or directed against political delinquents. "For such purposes as these," says Mr. Bell, "the Bloodhound has been employed, at various times, in every part of the United Kingdom: in the clan feuds of Scotland, in the border contests of the debatable land of the two kingdoms, and in the unhappy Irish rebellion, its extraordinary powers have been taken advantage of without much regard to the claims either of justice or of mercy. Such scenes, however, have now become mere matter of history and of tradition; for, on the one hand, the improvements which have taken place in the breed of hounds for the purposes of the chase, and on the other, the gradual introduction of a more regular system of police, aided, we may hope, by some amelioration in the feelings of the people, have annihilated the use of the Bloodhound in both the objects for which it was formerly employed."

BLUE-BIRD. (*Sialia.*) This bird is as well known in America as the Redbreast is with us, and its habits of familiarity with man in the summer are on a par with those of our friendly visitor in the winter.

It is about seven inches and a half long, and the whole of the upper part of the body is of a rich sky-blue shot with purple. The bill and legs are black; the wings of a

BLUE-BIRD.—(*SIALIA SIALIS.*)

dusky black at the tips, and the shafts of the wings and tail feathers are black; the throat, neck, breast, and sides partially under the wings, reddish chestnut; the belly and vent white. It arrives in the United States early in the spring, and takes its departure in November. Its food consists of large beetles, spiders, and other insects, besides berries, seeds, and fruits. The nest is generally built in holes of trees; and the male is most assiduous in attentions to his mate; the eggs are of a pale blue colour; and it often happens that two or three broods are produced in one season.

BLUE [BUTTERFLY]. A name applied to several species of Butterflies, of the genus *Polyommatus*.

BLUE-BREAST. (*Cyanocitta stelleri.*) This elegant little bird inhabits different parts of Europe, and is mostly found on the borders of forests. It is five inches and a half in length, of which the tail occupies two and a quarter. The head, back, and wing-coverts are ashy-brown, mottled with a darker tint; a reddish-white line passes above the eyes; a brilliant sky-blue covers the throat and half-way down the breast; this is set off by a spot of the most dazzling white, the size of a pea, placed precisely over the larynx, which, enlarging and diminishing successively by the movement of this part when the bird sings, produces the most beautiful effect. The blue passes into a black band, and the latter into a fine orange; the belly is dusky white; the thighs and sides are reddish; and the quill feathers dark brown. Some males have two little white spots on the throat, and some even three; but some have none. The food of the Blue-breast consists of flies, the larvæ of insects, and worms. The nest is built in bushes and in the holes of trees; and the eggs are of a greenish hue. The females, when young, are of a celestial-blue tint on the sides of the throat; and when very old they have the throat sometimes of a very bright blue.

BOA CONSTRICTOR. Of all the reptiles that exist, none equal in size and power the genus *Boa*; some of them being occasionally met with from thirty to thirty-five feet in length, and of a strength so prodigious as to be able to destroy deer, oxen, and other large and powerful animals, by enveloping

BOA CONSTRICTOR.

them in their ample folds, crushing them to death, and, lubricating the bodies with their saliva, swallowing them at their leisure. In this tribe the branches of the upper and lower jaw, throughout the whole length, as well as the palate bones, are armed with pointed, recurved, solid, and permanent teeth, forming four nearly equal rows above, and two below. They have the tympanic bone or pedicle of the lower jaw moveable, which is itself almost wholly suspended to another bone, analogous to the mastoid, attached to the skull by muscles and ligaments, which contribute to its mobility. The branches of this jaw are not united, and those of the upper jaw are attached to the intermaxillary bone only by ligaments, so that these animals can dilate the mouth sufficiently to swallow bodies much larger than themselves. They are further distinguished by having the *scuta* on the other part of the tail single; a hook on each side of the vent; the tail prehensile; the body compressed, and largest in the middle, and with small scales, at least on the posterior part of the head.

Enormous as the size and power of such animals must be, according to the latest and best authenticated statements of eye-witnesses, yet, if we may rely on the accounts of ancient writers, there was a time when serpents far more terrific committed their hideous ravages, and kept whole armies in dismay. One of this kind is described as having had its lair on the banks of the Bagradas, near Utica, and to have swallowed many of the Roman soldiers in the army of Regulus, to have killed others in its folds, and to have kept the army from the river; till at length, being invulnerable by ordinary weapons, it was destroyed by heavy stones slung from the military engines used in sieges: but, according to the historian Livy (quoted by Valerius Maximus), the water, were polluted with its gore, and the air with the steams from its corrupted carcass, to such a degree that the Romans were obliged to remove their camp, taking with them, however, the skin, 120 feet in length, which was sent to Rome. That none of such frightful dimensions now infest the inhabited parts of the earth we have abundant evidence; and there is good reason to believe that as cultivation and population have increased, the larger species of noxious animals have been expelled from the haunts of mankind, and driven into more distant and uncultivated regions.

Some species of the genus *Boa* are found in the vast marshes and swamps of Guiana, and

other hot parts of the American continent: others are natives of India, Africa, and the larger Indian islands. They are at once pre-eminent from their superior size and their beautiful colours; and though destitute of fangs and venom, nature has endowed them with a degree of muscular power which seems to defy resistance. The ground colour of the whole animal, in the younger specimens, is a yellowish grey, and sometimes even a bright yellow, on which is disposed along the whole length of the back a series of large, chain-like, reddish-brown variegations, leaving large open oval spaces of the ground colour at regular intervals: the largest or principal marks composing the chain-like pattern above mentioned are of a squarish form, accompanied by large triangular and other shaped spots, the exterior of the larger ones being generally of a much darker cast, and the ground colour immediately next to them considerably lighter than on other parts, thus constituting a general richness not easily described.

We cannot reflect upon the history of these great reptiles without being struck with their peculiar adaptation to the situations in which they are commonly most abundant. In regions bordering on great rivers, which annually inundate vast tracts of country, these serpents live securely among the trees with which the soil is covered, and are capable of enduring very protracted hunger, without much apparent suffering, or diminution of vigour. Noxious as such districts are to human life, they teem with a gigantic and luxurious vegetation, and are the favourite haunts of numerous animals, preyed upon, and, to a certain degree, restricted in their increase, by the *boas*. In such situations the *Boa Constrictor* lurks, or winds itself round the trunk or branches of a tree, until some luckless animal approaches; then, suddenly relinquishing his position, swift as lightning he seizes the victim, and coils his body spirally round its throat and chest, until, after a few ineffectual cries and struggles, the animal is suffocated and expires. The prey is then prepared for being swallowed, which the creature accomplishes by pushing the limbs into the most convenient position, and then covering the surface with a glutinous saliva. The reptile commences the act of deglutition by taking the muzzle of the prey into its mouth, which is capable of vast extension; and, by a succession of wonderful muscular contractions, the rest of the body is gradually drawn in, with a steady and regular motion.

In Mr. McLeod's narrative of the voyage of H. M. ship *Alceste* to China, is the following characteristic account of the *Boa*, as observed on shipboard. "Notwithstanding the crowded state of the *Cæsar*," (the vessel in which the crew of the *Alceste* returned, their own having been wrecked), "two passengers, of rather a singular nature, were put on board at Batavia for a passage to England: the one, a snake of that species called *Boa Constrictor*; the other, an *Ourang Outang*. The former was somewhat small of his kind, being only about sixteen feet long, and of about eighteen inches in circumference; but

his stomach was rather disproportionate to his size, as will presently appear. He was a native of Borneo, and was the property of a gentleman (now in England), who had two of the same sort; but, in their passage up to Batavia, one of them broke loose from his confinement, and very soon cleared the decks, as everybody very civilly made way for him, and ran up the rigging, or to some other place of security. Not being used to a ship, however, or taking, perhaps, the sun for a green field, he sprawled overboard, and was drowned. He is said not to have sunk immediately, but to have reared his head several times, and with it a considerable portion of his body, out of the sea. His companion, lately our shipmate, was brought safely on shore, and lodged in the courtyard of Mr. Davidson's house at Ryswick, where he remained for some months, waiting for an opportunity of being conveyed home in some commodious ship sailing directly for England, in which he was likely to be carefully attended to. This opportunity offered in the *Cæsar*, and he was accordingly embarked on board of that ship with the rest of her numerous passengers. During his stay at Ryswick he is said to have been usually entertained with a goat for dinner, once in every three or four weeks, with occasionally a duck or a fowl, by way of a dessert. He was brought on board shut up in a wooden crib or cage, the bars of which were sufficiently close to prevent his escape; and it had a sliding door, for the purpose of admitting the articles on which he was to subsist; the dimensions of the crib were about four feet high, and five feet square; a space sufficiently large for him to coil himself round with ease. The live stock for his use during the passage, consisting of six goats of the ordinary size, were sent with him on board, five being considered as a fair allowance for as many months. At an early period of the voyage we had an exhibition of his talent in the way of eating, which was publicly performed on the quarter-deck, upon which he was brought. The sliding door being opened, one of the goats was thrust in, and the door of the cage shut. The poor goat, as if instantly aware of all the horrors of its perilous situation, immediately began to utter the most piercing and distressing cries, butting instinctively, at the same time, with its head towards the serpent, in self-defence. The snake, which at first appeared scarcely to notice the poor animal, soon began to stir a little, and, turning his head in the direction of the goat, he at length fixed a deadly and malignant eye on the trembling victim, whose agony and terror seemed to increase; for, previous to the snake seizing its prey, it shook in every limb, but still continued its unavailing show of attack, by butting at the serpent, which now became sufficiently animated to prepare for the banquet. The first operation was that of darting out his forked tongue, and at the same time rearing a little his head; then suddenly seizing the goat by the fore leg with his mouth, and throwing it down, it was encircled in an instant in his horrid folds. So quick, indeed, and so in-

stantaneous was the act, that it was impossible for the eye to follow the rapid convolution of his elongated body. It was not a regular *serpentine*-like turn that was formed, but resembling rather a knot, one part of the body overlaying the other, as if to add weight to the muscular pressure, the more effectually to crush his object. During this time he continued to grasp with his fangs, though it appeared an unnecessary precaution, that part of the animal which he had first seized. The poor goat, in the mean time, continued its feeble and *half-stifled* cries for some minutes, but they soon became more and more faint, and at last it expired. The snake, however, retained it for a considerable time in his grasp, after it was apparently motionless. He then slowly and cautiously unfolded himself, till the goat fell dead from his monstrous embrace, when he began to prepare himself for swallowing it. Placing his mouth in front of the dead animal, he commenced by lubricating with his saliva that part of the goat; and then taking its muzzle into his mouth, which had, and indeed always has, the appearance of a raw lacerated wound, he *sucked it in*, as far as the horns would allow. These protuberances opposed some little difficulty, not so much from their extent, as from their points; however, they also, in a very short time, disappeared; that is to say, externally; but their progress was still to be traced very distinctly on the outside, threatening every moment to protrude through the skin. The victim had now descended as far as the shoulders; and it was an astonishing sight to observe the extraordinary action of the snake's muscles when stretched to such an unnatural extent—an extent which must have utterly destroyed all muscular power in any animal that was not, like himself, endowed with very peculiar faculties of expansion and action at the same time. When his head and neck had no other appearance than that of a serpent's skin, stuffed almost to bursting, still the workings of the muscles were evident; and his power of suction, as it is erroneously called, unabated; it was, in fact, the effect of a contractile muscular power, assisted by two rows of strong hooked teeth. With all this he must be so formed as to be able to suspend, for a time, his respiration, for it is impossible to conceive that the process of breathing could be carried on while the mouth and throat were so completely stuffed and expanded by the body of the goat, and the lungs themselves (admitting the trachea to be ever so hard) compressed, as they must have been, by its passage downwards.

The whole operation of completely gorging the goat occupied about two hours and twenty minutes: at the end of which time the tumefaction was confined to the middle part of the body, or stomach, the superior parts, which had been so much distended, having resumed their natural dimensions. He now coiled himself up again, and lay quietly in his usual torpid state for about three weeks or a month, when, his last meal appearing to be completely digested and dissolved, he was presented with another

goat, which he killed and devoured with equal facility. It would appear that almost all he swallows is converted into nutrition, for a small quantity of calcareous matter (and that, perhaps, not a tenth part of the bones of the animal), with occasionally some of the hairs, seemed to compose his general faeces;—and this may account for these animals being able to remain so long without a supply of food."

There are many other serpents of the species *Boa*; of which a short notice is necessary.—1. The **SPOTTED BOA**. (*Boa seytale*.) This is sometimes scarcely inferior to the *Boa Constrictor*, and is of similar habits. It is of a grey colour, marked with large orbicular spots, interspersed with other marks and variegations. It is found in many parts of South America.—2. The **RINGED BOA**. (*Boa conchris*.) This also grows to a large size, though considerably smaller than either of the before mentioned; and may be easily distinguished by the regular distribution of its marks and colours. On the back is a continued series of very large blackish circles from head to tail, while along the sides are interspersed several kidney-shaped spots, with their centres white. It inhabits South America.—3. The **EMBROIDERED BOA**. (*Boa Phrygia*.) There exists scarcely a more truly elegant species in the whole serpent tribe than this. It is nearly four feet long; the ground colour white, the back being tinged with a cast of yellowish brown; while along the whole upper part is a continued series of black variegations, bearing a striking resemblance to embroidery. It is a native of the East Indies.—4. **CANINE BOA**. (*Boa canina*.) This beautiful snake is about four feet in length; the head is large, and shaped like that of a dog; the general colour a bright Saxon green, with transverse white bars down the back, the edges of which are of a deeper green than the ground colour of the body; the belly is white. This species belongs to South America.—5. The **GARDEN BOA**. (*Boa hortulana*.) The ground colour of this species is a light yellowish brown, or sometimes pale violet, variegated with a dark purplish brown pattern resembling rich embroidery. The head is broad, and the neck slender. There are several others, but the foregoing will convey a sufficient idea of them.

BOAR. The male of Swine. [See *Hog*.]

BOAR-FISH. (*Capros aper*.) An Acanthopterygious fish, resembling the *Dory* in its general outline, and in having the first

BOAR-FISH.—(CAPROS APER.)

dorsal fin deeply notched; but it has no spines along the dorsal or anal: The fins are covered with rough scales; the mouth projects considerably; and the fins are entirely without filaments. The flesh of the Boar-fish is but in little esteem.

A very few instances of the presence of this rare fish on the British coasts have been recorded. We believe the last was by Waring Kidd, Esq., and the following account of it appeared in "The Zoologist," p. 191:—"On the 6th of March, 1842, a fish six inches and a half in length and three inches in width, of most brilliant colours, was picked up by a fisherman. It was alive when found: the colours were bright orange and lake. The fish was taken by the person who picked it up to Mr. Griffin, the principal fish-monger of Brighton; he took it to the Pavilion, where it was presented to her Majesty. It was immediately recognised by His Royal Highness Prince Albert (the Prince being a good naturalist) as the Boar or Hog fish of the ancients, a species very scarce on the British coasts. His Royal Highness, wishing to have it preserved, sent it here; as it was for Her Majesty, it gave me great pleasure that I succeeded so well, both in preserving the colours and in showing the peculiarity of the mouth, which the fish has the power of extending and contracting at will. When extended, it takes the form of a hog's snout; hence the name of Boar-fish. I suspended the fish under a glass shade, and placed a few seaweeds, &c. on the stand. When quite completed, I made a painting of it, and succeeded in representing the colours pretty correctly."

BOAT-BILL. (*Cancroma*.) A genus of Grallatorial birds, distinguished by their

BOAT BILL.—(CANCROMA COELESTIS.)

very remarkable bill, the form of which by some is likened to a boat with its keel upwards, and by others to the bowls of two spoons, the concave sides of which are placed in contact. The mandibles are very stout and sharp-edged, and the upper one has a projecting point at the extremity. The feet have four toes, all of them long, and without a connecting membrane; for which reason these birds perch on the branches of trees by the sides of rivers, so that they may

pounce upon the fish as they swim beneath. The species *Cancroma cochlearia* is the size of a domestic fowl. In the male, the forehead, and upper parts of the neck and breast, are dirty white; and from the head depends a long crest of black feathers. The female has the top of the head black, without the elongated crest. It inhabits Guiana, Brazil, and other parts of South America. Close to this comes the gigantic Whale-headed Stork, or *Baleniceps*, a bird frequenting the upper waters of the Nile, and subsisting on fishes, young crocodiles, lepidosirens, &c. Two living examples were lately introduced into the Zoological Society's menagerie. [See *BALENICEPS* IN SUPPLEMENT.]

BOAT-FLY. (*Notonecta*.) An aquatic Hemipterous insect, the back of which is shaped like the bottom of a boat; and the hind legs, which are thrice as long as the fore, aptly enough resemble a pair of oars. The legs of the hinder pair have a fringe of bristles along their edge; by which the surface, with which they strike the water in swimming, is greatly increased. Their general form is well adapted for rapid progression in water; and it is from the peculiar aspect and movement of the body that they have received their name. They swim on their backs; and their eyes are so placed that they are able to see both above and below the surface of the water, so that at the approach of danger they instantly descend, and are out of sight.

BOB-O-LINK. [See *RICE BUNTING*.]

BODIAN. There are several species of fish, of the Carp kind, bearing this name. They are natives of the Indian and American seas; and vary from one foot to three feet in length.

BOMBUS. The Humble-bee [which see].

BOMBYCIDÆ. A family of Lepidopterous insects, one of the most interesting of which is the *Bombyx Mori*, well known as the Moth to which the Silkworm turns. The caterpillars of most of the species are hairy, and assume the pupa state in a cocoon spun for its protection.

BOMBYCHLLA. The name of a genus of birds placed by Cuvier among the Dentirosal genera of his second order of *Passeres*. They may be distinguished at first sight from any other birds by a remarkable appendage on the tips of some of the quills, which has very much the appearance of red sealing-wax. Their principal generic characters are—Bill short, slightly depressed and triangular at the base; above convex, towards the tip bent down, and emarginate on each side. Nostrils oval, covered with small feathers. Feet four-toed, with the outer one connected at the base. [See *WAXWING*.]

BOMBYLIDÆ. A family of insects of the order *Diptera*. They have an appearance somewhat resembling that of the smaller kinds of Humble-bees, being thickly covered with erect downy hair: their flight is rapid; and they may be frequently observed to hang, as if suspended, over a flower, sip-

ping its sweets by means of their long proboscis, while their wings vibrate so rapidly as to be scarcely discerned to move; then darting to another with such rapidity that the eye cannot follow them. They frequent gardens, open parts of woods, and sunny banks; and are most common in spring.

BOMBYX. [See *SILK-WORM*.]

BONASSUS. [See *BISON*.]

BONITO. (*Thynnus*.) A handsome fish of the order *Acanthopterygii*, a native of the Mediterranean, and a rare visitant of our

BONITO.—(*THYNNUS PELAMIS*.)

shores. It is about three feet long; has a sharp head, a small mouth, large gills, full silvery eyes, and a crescent-shaped tail. It has no scales except on the middle of the sides, where a line of gold colour runs from the head to the tail. It is greenish on the back and sides, but its belly is of a silvery white; and it is distinguished by its great activity and voracity, being one of the chief enemies of the flying-fish. It is also called the Striped Tunny.

BOOBY. (*Sula fusca*.) The name given by navigators to a large bird, a species of Gannet, which inhabits the desolate islands

BOOBY.—(*SULA FUSCA*.)

and coasts of most warm climates. The name was naturally acquired from their apparent stupidity, in quietly sitting on the shore, or perching on the yard of a ship, till knocked on the head, or taken away by any one who may attempt it. [See *GANNET*.]

BOOK-WORM. A name given to various species of insects in the larva state, in which they destroy books and papers, by boring into them; such as the *Plinida*, *Anobium*, &c.

BOOPS. A genus of small Acanthopterygious fishes, found mostly in the Mediterranean. The species are generally of brilliant colouring, and characterized by a small mouth, large eyes, and a rounded form.

BOPYRUS. A parasitic Crustacean, of the order Isopoda, of which three or four species are known. They fasten on the prawn, hermit crab, and other Crustacea. The sexes differ very much in appearance. The *B. Squillarum* is far from uncommon in this country: it causes swellings on the side of the carapace of the common *Palaemon Squilla*.

BOS. The scientific name for a genus of hollow-horned ruminating quadrupeds, which in their domesticated state contribute most materially to the comforts and conveniences of man. [See OX; BISON, &c.]

BOSTRICHUS; BOSTRICHIDÆ. A genus and family of Coleopterous insects, of the group *Xylophila*, some species of which are highly destructive of timber. These Beetles usually live in wood, which their larvæ

XYLOPHILUS FLABELLIFORMIS — AN ANTENNA MAGNIFIED.

pierce in every direction; and when abundant in forests, especially those of pines and firs, they destroy immense numbers of trees in a few years. One of the most destructive species is the *Bostrichus Typographicus*, or the Typographer Beetle, which has at different times ravaged the forests of Germany. It devours, both in the larva and perfect

TYPOGRAPHUS BEETLE

states, the soft wood beneath the bark, which is most essential to the vegetative process, and thus causes the death of the tree. The females attack the crevices of the bark, and perforate it in diverging lateral channels, in which from sixty to eighty eggs are deposited. At the end of fifteen days the larvæ are hatched, and forthwith commence the work of destruction, each gnawing a serpentine gallery between the bark and the wood, and gradually enlarging its burrow until the period when it is ready to pass into the pupa state; when, having finally become a perfect beetle, it directly bores through the portion of the tree which remains between the wood and the outer bark, and escapes through a small circular aperture in the latter. There appears to be no remedy when the trees are

once attacked but to cut down the trees, bark them and burn the bark, and to remove all felled timber without delay.

BOTATRISSE. The Eel-pout. [See EEL.]

BOTAURUS. [See BITTERN.]

BOTRYLLUS. A genus of Molluscan animals termed *Aggregated Ascidians*, which at first float free and separate, but at a certain period of their existence unite to form one common mass. The aggregated animals thus found together are almost always very small, soft, irritable, and contractile, changing their form with the slightest movement. [See ASCIDIA.]

BOTS. The larvæ or caterpillars of the Gad-fly, belonging to the order *Diptera*, genus *Æstrus*, of which there are numerous species. They infest horses and cattle; and are distinguished by passing the larval state of their existence within some animal, and feeding on the juices or substance of that animal. [See *ÆSTRUS*; BREEZE-FLY, &c.]

BOTTLE-FISH. [See SACCOPHARYNX.]

BRACHELYTRA. An extensive group of Coleopterous insects, distinguished by the elongate form of the body and the shortness of the wing-cases. They run and fly with equal agility; preying upon decaying animal and vegetable matters, especially fungi, agarics, &c., in which they chiefly reside; they are also found in profusion under heaps of putrescent plants. They are decidedly carnivorous; some species are, however, found in flowers, others upon the margins of running streams, and others under the bark of decaying trees. — One of the commonest, and at the same time most formidable-looking members of the family, is a black species, rather more than an inch long, commonly called the "Devil's Coach-horse" (*Goeius olens*). This is frequently to be seen running about garden walks, cellars, and dusty roads. True to the habits of the family, on the least approach of danger it immediately puts itself into a posture of defence, throws the tall over the head like a scorpion, protrudes the anal rings, elevates its head, and opens its long and powerful jaws. — The geographical range of this group of insects is principally confined to the temperate climes of the northern hemisphere; a few species, however, have been received from tropical climates, which are remarkable for the singularity of their forms and the splendour of their colours; but it rarely happens that the exotic species exceed those of our own country in size.

BRACHINUS. A genus of Coleopterous insects, with truncated elytra and a smallish thorax; of which the *Brachinus crepitans* is the most common. This insect, which is found under stones, is about half an inch long; the head, thorax, and legs are of a yellowish red colour; the wing-cases greenish, or blue black; and the antennæ reddish. They possess a remarkable power of violently expelling from the anus a pungent acrid fluid, accompanied by a loud report, considering the size of the insect; whence its common name of *Bombardier Beetle*.

BRACHIONUS. A genus of minute animals, found in stagnant fresh water and in sea water. [See ENTOMOSTRACA.]

BRACHIOPODA. A class of Acephalous or headless molluscous animals, with bivalve shells. They are characterized by having the mantle organized so as to be serviceable for respiration, and by having two long, fleshy, ciliated, spiral arms, but no foot. They have no organs of locomotion, but live fixed to submarine bodies. The species are numerous and widely diffused; and, though comparatively low in the scale of creation, the class is interesting both to the physiologist and the geologist.

BRACHY CERUS. A genus of Coleopterous insects, the species of which are apterous, and very rough. They live upon the ground, and appear to be peculiar to the south of Europe and Africa, particularly abounding in the latter quarter of the globe.

BRACHYPTERES. The name given by Currier to that class of birds generally known as "Divers."

BRACHYTELES. A genus of *Quadrumanas*, so named on account of the very small development of the thumb.

BRACON. A genus of Hymenopterous insects, allied to the Ichneumons; remarkable for the hiatus which exists between the mandibles and the clypeus.

BRADYPUS. [See SLOTH.]

BRAMHIN BULL, INDIAN OX, or ZEBU. (*Bos Indicus.*) There is a very considerable difference in the various domesticated Asiatic oxen, as to the size and direction of the horns: some are short and suberect; others incline inwards; but they are generally distinguished by a fatty elevated hump upon the withers. The ears are pendulous, and the dewlap is usually very largely developed. Their colour varies from a light ashy grey to a milk white, and their size from the stature of an ordinary bull to

BRAMHIN BULL.—(*BOS INDICUS.*)

that of a Shetland pony. The limbs of all are light and elegant. The flesh is neither so sweet nor so good as that of the common ox, except the hump, which is allowed on all hands to be delicious when properly cooked. In many parts of India the Zebu is used as an animal of burden, and, when harnessed to a carriage, it will travel, at an easy

rate, about thirty miles a day. Antient writers speak of its performing about double that distance; but if that were true, it must have lost much of its fleetness. The Hindoos regard them as animals worthy of veneration, and consequently consider it sinful to slaughter them; they do not, however, generally object to work them. "They are spread," says Mr. Bennett, "over the whole of Southern Asia, the islands of the Indian Archipelago, and the eastern coast of Africa from Abyssinia to the Cape of Good Hope."

BRAMBLING. (*Fringilla montifringilla.*) This bird, which is also called the Mountain-Finch, is larger than the chaffinch. The top of the head and the back are of a glossy black colour, slightly edged with a yellow brown; the throat and breast are orange, as are the lesser coverts of the wings; but those which rest on the quill feathers are barred with black, tipped with orange; and the tail is slightly forked.

BRANCHIOPODA. An order of Crustaceous animals, in which the locomotive extremities fulfil the functions of gills. These Crustaceans, which are for the most part microscopic, are always in motion when in an animated state, and are generally protected by a shell or crust in the shape of a shield, or of a bivalve shell, and are furnished sometimes with four, sometimes with two antennae. Their feet vary in number, some having not less than a hundred. A great portion have only one eye.

BRANCHIOSTEGI. A tribe of Cartilaginous fishes, comprehending those in which the gills are free, and covered by a membrane; including the Sturgeon and Chimæra [which see].

BREAM. (*Abramis brama.*) A fish of the Carp family, and by anglers often called the Carp-bream; found in lakes, and in the deepest parts of still rivers. The body is extremely deep and thin in proportion to its

BREAM.—(*ABRAMIS BRAMA.*)

length, and the back much elevated. Length two feet to two feet and a half; colour olive, with a pale or flesh-coloured tinge on the under parts; scales large; dorsal fin rather small, and situated a little beyond the middle of the back; anal fin extending from the vent nearly to the tail, which is pretty deeply forked. Its flesh is generally considered coarse and extremely insipid.

The SEA BREAM (*Pagrus centrodontus*) is a common fish in the Mediterranean, nor is it by any means uncommon on the southern and western coasts of England, especially

during summer and autumn. The spawn is shed in the beginning of winter in deep water; and it retreats altogether from our shores in severely cold weather. The young of this fish are commonly known by the name of *Chads*. The Sea bream is not very highly esteemed for the table, either fresh or salted.

BREEZE-FLY. (*Estrus*; *Estridae*.) The insects we are about to describe are produced from larvæ which when existing in horses are termed *bots*; in sheep, *maggots*; and in cows and oxen, *cornils*; and these three represent three divisions of the family, differing essentially in their history. The perfect insect produced from each kind of larva is properly termed a Breeze-fly. Before we proceed farther, however, we beg to state that the observations which follow are taken from Mr. Newman's History of Insects, who quotes as his authority "An Essay on the Bots of Horses and other animals, by Bracy Clark, F. L. S."

"The opinions of the Breeze-fly of the horse, or *bot*, as it is usually termed, as to the benefit or injury derived from it, are very opposite; some observers go so far as to assert that the larvæ occasionally completely perforate the stomach of the horse, causing disease, pain, and even death; others regard them as perfectly innocuous; and one author (Mr. Bracy Clark), whose careful and laborious investigations entitle his opinions to the greatest respect, believes the effect of bots to be salutiferous rather than otherwise; and from his masterly essay the following particulars are extracted.

"The female fly, in approaching the horse for the purpose of oviposition, carries her body nearly upright in the air, the protruded ovipositor being curved inwards and upwards. Suspending herself for a few seconds before the part of the horse on which she intends to deposit the egg, she suddenly darts upon it, and leaves the egg adhering to the hair: she hardly appears to settle, but merely touches the hair with the egg held out on the extreme point of the ovipositor, the egg adhering by means of a glutinous liquor with which it is covered. She then leaves the horse at a small distance, prepares a second egg, and, poising herself before the part, deposits it in the same way: the liquor dries, and the egg becomes firmly glued to the hair. This is repeated till four or five hundred eggs are sometimes placed on one horse. The skin of the horse is usually thrown into a tremulous motion on the touch of the insect, which merely arises from the very great irritability of the skin and cutaneous muscles at this season of the year, occasioned by the heat and continual teasing of the flies, till at length these muscles appear to act involuntarily on the slightest touch of any body whatever.

"The fly does not deposit her eggs at random on the horse's body; but selects those parts which are most likely to be nibbled by the horse: the inside of the knee is frequently chosen, but all naturalists must have remarked how commonly the eggs of the bot are deposited on that part of a horse's shoulder which he can never reach with his

mouth, and thus, to a casual observer, it would seem that they must perish, and fail in the object for which their parent designed them. Now there is a provision of nature which exactly counteracts this difficulty. When horses are together in a pasture, and one of them feels an irritation on any part of the neck or shoulder which he cannot reach with his mouth, he will nibble another horse in the corresponding part of his neck or shoulder, and the horse so nibbled will immediately perform the kind office required, and begin nibbling away in the part indicated. The horses, when they become used to this fly, and find it does them no injury by sucking their blood, hardly regard it, and do not appear at all aware of its object.

"When the eggs have remained on the hairs four or five days, they become mature, after which time the slightest application of warmth and moisture is sufficient to bring forth in an instant the latent larva. At this time, if the lips or tongue of the horse touch the egg, its operculum is thrown open, and the young larva liberated: this readily adheres to the moist surface of the tongue, and is from thence conveyed with the food to the stomach. It is worthy of remark, that it is probable the greater part of the eggs deposited by this fly are taken up in consequence of the irritation of other flies, as the *Tabani* and *Stomoxides*, which, by perpetually settling on the skin, occasion a horse to nibble himself on those parts, and thus receive the larvæ on the tongue and lips, whence they are introduced into the stomach. * * * The larva, when matured, quits the stomach of the animal and falls to the ground, and finding a convenient place of retreat, undergoes its change to a chrysalis, the skin then losing its organization, and changing in colour from a whitish red to a reddish brown. After remaining torpid in the chrysalis state a few weeks, the superfluous moisture being removed and the parts of the future insect hardened by drying, it bursts from its confinement, and the fly makes its exit at the small end of the case. A few hours after quitting their shell they become dry, take wing, and seek their mates.

"A second species of Breeze-fly has a still more wonderful history: its eggs are laid in the nostrils of sheep, from one to seven or eight in each individual, and these on becoming larvæ, enter the frontal and maxillary sinuses, and even the horns, and feed on their secretions: when the larvæ are young they are perfectly white and transparent, except two small black horny plates: as they increase in size the upper surface becomes marked with two transverse brown lines on each segment, the anterior being shorter and narrower than the posterior; and some spots are also observable on the sides. The body consists of twelve segments besides the head. These larvæ move with considerable activity, holding with their tentacula to a fixed point and drawing up the body. When full grown the larvæ fall through the nostrils of the sheep, and change to the pupa state lying on the earth or adhering to the side of a blade of grass: in

about two months the case of the chrysalis opens, and the fly makes its appearance. Sheep are exceedingly annoyed by these flies, and to avoid them lie down in ruts with their heads close to the ground; at other times we see them huddled together under trees in a dense mass or phalanx, the nose of each being pushed into the fleece of another.

"There is a third species of Breeze-fly, far more formidable than either of those previously described: its eggs are laid on the backs and sides of cows and oxen, and the larvæ hatched from them enter the hide, producing tumours as large as pigeons' eggs. The larva itself is of an oblong figure, larger at one extremity than at the other; the body is divided into ten or twelve segments by transverse bands, and these are again intersected by six longitudinal lines, which purse up the skin, and produce along the sides a series of mammiform protuberances, each possessing at its extremity a respiratory pore; on each segment of the body may be observed ridges, or dotted prominent lines, interrupted however by the longitudinal lines already noticed: there are in pairs a narrower and broader line of minute dots or points; the narrower line is found, under a lens, to be formed of hooks bent towards the posterior extremity of the insect; the broader lines consist of smaller hooks bent in an opposite direction, or towards its head: it is probably by the aid of these hooks that the animal raises or depresses itself in the tumour, and finally, when mature, effects its escape.

"The food of the larva appears to be the pus or matter surrounding it in the tumour in which it exists: as regards the period of its continuing to feed we have little satisfactory information. Its colour when young is white, but as it advances towards maturity it becomes browner, and finally of a deep dark brown, approaching to black: having attained its full size, it presses itself against the upper part of the tumour, and by some unknown process makes an aperture in the hide of about sufficient size to admit a pea; through this the larva wriggles itself a segment at a time until it comes quite out, and falling to the ground seeks a convenient retreat in which to become a chrysalis.

"The chrysalis is of a dark brown colour, and in figure somewhat resembles the half of a walnut-shell, being narrower at one end than the other, flat on one side, and very rounded and convex on the other; after lying on the ground for some weeks, a portion of the indurated skin or cover, of a triangular shape, is forced up at the smaller end, and through the aperture thus occasioned the fly emerges. The fly is large and handsomely coloured; although the presence of the larvæ in the backs of cattle is frequently observable, the insect in its perfect state is rarely met with, and very few of our cabinets possess good specimens; it flies with rapidity, but apparently without noise, and never ventures over water.

"The act of oviposition appears to be attended with severe suffering, or apprehension at least, which makes the cattle run

wild and furious, and gad or stray from the pastures, and hence the ancient epithet of gad-fly. When oxen are yoked to the plough, the attack of this fly is attended with real danger, since they become perfectly uncontrollable, and often run directly forwards through the hedges, or whatever obstructs their way. On this account many ploughs are provided with a contrivance for setting the oxen immediately at liberty. When the cattle are attacked by this fly, it is easily known by the extreme terror and agitation of the whole herd; the unfortunate object of the attack runs bellowing from among them, and seeks a refuge in the nearest water; the tail becomes rigid, and is brandished aloft, or held straight out from the body. Its frightened companions follow in the rear of the animal attacked, and a wild and apparently unmeaning chase takes place, which, from the inelegant gallop of the cows, has often a very ludicrous effect.

BRENT GOOSE. A much smaller bird than the common wild goose, but with longer wings; and it traverses greater distances in its migrations. Its breeding places are in the far north; but it migrates for the winter to France, England, Ireland, &c. The head, neck, bill, and upper part of the breast are black; and on each side of the slenderest part of the neck: the lower part of the breast, the scapulars, and coverts of the wings are ash-coloured; the feathers, both above and below the tail, are white; and the tail, the quill feathers, and the legs are black.

BRENTIDÆ, or BRENTIDÆ. A family of Coleopterous insects, which are among the most remarkable of the beetle tribe, and almost entirely confined to tropical climates. Distinguishing characters:—body much elongated; tarsi with the penultimate joints bilobed; antennæ filiform, or in some with the terminal joint formed into a club; proboscis projecting horizontally; palpi minute. They are found crawling on trees, or under the bark, and sometimes on flowers. Their general colour is black or brown, with red spots or markings.

Dr. Thaddeus Harris, librarian of Harvard College, gives a detailed account of a North American species, in his fine work on the Insects of Massachusetts. We somewhat condense his history of it. It is the *Brenthus septentrionalis*. The Northern *Brenthus*, so named because most of the other species are tropical insects, is of a mahogany brown colour; the wing cases are somewhat darker, ornamented with narrow tawny yellow spots, and marked with deep furrows, the sides of which are punctured. Its common length is about six-tenths of an inch, but much larger as well as smaller specimens frequently occur. The Northern *Brenthus* inhabits the white oak, on the trunks and under the bark of which it may be found in June and July, having then completed its transformations. The female, when about to lay her eggs, punctures the bark with her slender snout, and drops an egg in each hole thus made. The grub, as soon as it is hatched, bores into the solid wood, forming a cylindrical passage, which

It keeps clear by pushing its castings out of the orifice of the hole, as fast as they accumulate. These castings or chips are like very fine saw-dust; and the holes made by the insects are easily discovered by the dust around them. The grub is about an inch long and nearly cylindrical; the last segment is of a horny consistence, and is obliquely hollowed at the end, so as to form a kind of gouge or scoop, the edges of which are furnished with little notches or teeth. It is by means of this singular-scoop that the grub shovels the minute grains of wood out of its burrow. The pupa, which is of a yellowish white colour, is met with in the burrow formed by the larva; the back is furnished with transverse rows of little thorns or sharp teeth, and there are two larger thorns at the extremity of the body. These minute thorns probably enable the pupa to move towards the mouth of its burrow when it is about to be transformed, and may serve also to keep its body steady during its exertions in casting off its pupa-skin. These insects are most abundant in trees that have been cut down for timber or fuel, which are generally attacked the first summer after they are felled; it has also been ascertained that living trees do not always escape, but those that are in full vigour are rarely perforated by grubs of this kind.

BREVIPENNES. The term given to the first family of *Still-birds*, the shortness of whose wings are inadequate to perform the function of flight; the weight of their massive bodies appearing to require more muscular power to support them in the air than nature has furnished them with. The pectoral muscles are reduced to extreme tenuity; but the muscles of the thighs and legs are of an enormous thickness. (See *OSTRICH*, *CASSOWARY*, &c.)

BRILL, or PEARL. (*Pleuronectes rhombus*.) In its general form this fish resembles the Turbot, but is inferior to it both in size and quality. It is distinguished from the Turbot by the perfect smoothness of its skin, which is covered with scales of a moderate size, and by its pale brown colour above, marked by scattered yellowish or rufous spots; the lateral line, as in the Turbot, is first arched over the pectoral fins, and from thence runs straight to the tail. The Brill is taken on many parts of our coasts; the principal part of the supply for the London market being derived from the southern coast, where it is most abundant.

BRIMSTONE [BUTTERFLY]. A name applied to the *Gonepteryx Rhamni*.

BROCK. A local name given to the Badger. *Bura* alludes to a "stinking brock."

BRONTOZOOM. [See SUPPLEMENT.]

BRUCHUS: BRUCHIDÆ. A genus and family of Coleopterous insects, allied to the Weevils, and thus characterized: palpi obvious, filiform, not very minute; rostrum broad; labrum exerted; antennæ eleven-jointed, sub-clavate, with the club formed of distinct joints in some; filiform, or gra-

dually thicker towards their points, in others; serrated or pectinated; the anus naked; hind feet generally very large. The female deposits an egg in the young and tender germ of various leguminous or cereal plants, &c., upon which the larva feeds, and within

BRUCHUS SERRIPES.

which it undergoes its transformations: the perfect insect, in order to make its escape, detaches a portion of the epidermis like a small cup; hence the small holes often observed in peas, dates, &c. The family is very extensive. *Bruchus pisi*, Linn., which is two lines long, black, with grey spots on the elytra, in some years does great mischief to peas, particularly in North America. *Bruchus serripes*, the figure of which is here given, with the head and posterior limb, is a fine example of this family. By some authors it is placed in a separate genus.

BRUSH TURKEY. The New Holland Tallegalla. [See TALLEGALLA.]

BRYOZOA. [See SUPPLEMENT.]

BUBO. A subgenus of Owls. [See OWL.]

BUCCINUM. A genus of Molluscous animals called Whelks; the general characters of which are, that their mouths are an oblong or very lengthened oval, the upper parts of which are slightly beaked. In the Linnean system, the Buccina form a distinct genus of the univalve and spiral Testacea. Those species most usually met with on the coasts of the British isles are the brown, massy, waved, striated, reticulated, and small *Buccina*. The shell of the *Buccinum lapillus* (the common White Buccinum) is one of the shells from which the ancients are supposed to have extracted their indelible purple dye, called the Tyrian purple. The part containing the colouring matter is a longitudinal vein, just under the skin on the back, behind the head. If the vein is laid open with a needle, a tenacious yellow matter will flow, which being applied with a hair pencil to linen, silk, or paper, it will in a short time become of a bright yellow, will soon change to pale green, then assume a bluish cast, and afterwards a deep and brilliant purple.

We learn from Mr. Stevenson's interesting narrative of the erection of the Bell Rock light-house, that the *Buccinum lapillus* preys upon the Mussel (*Mytilus edulis*). Mr. S. says, "When the workmen first landed upon the Bell Rock, limpets of a very large size

were common, but were soon picked up for bait. As the limpets disappeared, we endeavoured to plant a colony of mussels, from beds at the mouth of the river Eden, of a larger kind than those which seem to be natural to the rock. These larger mussels were likely to have been useful to the workmen, and might have been especially so to the light-keepers, the future inhabitants of the rock, to whom that delicate fish would have afforded a fresh meal, as well as a better bait than the limpet; but the mussels were soon observed to open and die in great numbers. For some time this was ascribed to the effects of the violent surge of the sea, but the *Buccinum lapillus* (Purpura) having greatly increased, it was ascertained that it had proved a successful enemy to the mussel. The *Buccinum*, being furnished with a proboscis capable of boring, was observed to perforate a small hole in the shell, and thus to suck out the finer parts of the body of the mussel; the valves of course opened, and the remainder of the fish was washed away by the sea. The perforated hole is generally upon the thinnest part of the shell and is perfectly circular, of a chamfered form, being wider towards the outward side, and so perfectly smooth and regular as to have all the appearance of the most beautiful work of an expert artist. It became a matter extremely desirable to preserve the mussel, and it seemed practicable to extirpate the *buccinum*. But after we had picked up and destroyed many barrels of them, their extirpation was at length given up as a hopeless task. The mussels were thus abandoned as their prey, and in the course of the third year's operations, so successful had the ravages of the *buccinum* been, that not a single mussel of a large size was to be found upon the rock; and even the small kind which bred there, are now chiefly confined to the extreme points of the rock, where it would seem their enemy cannot so easily follow them."

BUCCO. A genus of birds, called *Barbets*, a name derived from the bristly feathers which surround the base of the bill, and project beneath the chin like a beard. [See BARBET.]

BUCEROS. [See HORNBILL.]

BUCK. The male of the Fallow Deer, the female of which is called a *Doe*. [See DEER.]

BUFFALO. (*Bos bubalus*.) A species of Ox, found in various parts of India; but in America the name of "Buffalo" is universally given to the Bison [which see]. The Buffaloes are of large size, but low in proportion to their bulk; they have no hump on the back, and only a small dewlap on the breast; the hide is generally black; the tail long and slender. They generally live in small flocks, but sometimes are found in herds of considerable numbers; frequenting moist and marshy situations, and preferring the coarse vegetation of the forest and swampy regions to that of open plains. They swim well, and cross the broadest rivers without hesitation; their gait is heavy, and they run almost always with the nose

horizontal, being principally guided by the sense of smelling. They are fierce and stub-

BUFFALO.—(BOS BUBALUS.)

born, and with difficulty subjugated.—The Arnee Buffalo (*Bos arni*) has horns of a prodigious size and length; the horns are turned laterally, flattened in front, and wrinkled on the concave surface. A pair of them are in the British Museum, each of which measures along the curve from base to tip, six feet three inches, and eighteen inches in circumference at the base.

This formidable animal is found wild in many parts of India, and also tame wherever the inhabitants have occasion for its services. Being extremely strong, they are employed in agriculture, and in drawing and carrying burdens, being guided by rings thrust through their noses. All Buffaloes are extremely fearful of fire; and they have a great aversion to red colours. In general, they are very inoffensive, if left undisturbed; but when wounded, or even fired at, their fury becomes ungovernable; they then tear up the ground with their fore-feet, make a horrid bellowing, and pursue the objects of their resentment with determined fury. [See BISON.]

BUFO. [See TOAD.]

BUG. (*Cimex*.) Of the numerous tribe of Hemipterous insects belonging to the genus *Cimex*, we may specify the troublesome and nauseous insect, the *Cimex lectularius*, or common domestic Bug. To give a very particular description of this noxious tormentor would be superfluous: it may be sufficient to observe, that it is of an oval shape, about the sixth of an inch long, of a compressed or

BUG.—(*CIMEX LECTULARIUS*.)

flat form, and of a reddish-brown colour. It is asserted, though it may be difficult to say how truly, that the Bug was scarcely known in England before the year 1670, having been imported from America among the timber used in rebuilding the city of London after the great fire of 1666; but it appears not to have been an uncommon pest

in several countries of Europe before that time. Its blood-sucking properties, and the offensive smell it emits when touched, are too well known to require comment. The female Bug deposits her eggs in the beginning of summer; they are very small, white, and of an oval shape; each is fixed to a small hair-like stalk, which is glutinous, and readily adheres to any thing it touches. The places in which the eggs are generally deposited are the crevices of bedsteads or other furniture, or the walls of a room. During the winter months these odious insects secrete themselves behind walls, old wainscoting, or any neglected places, where they are capable of bearing the most intense frost without injury, and on the return of warm weather again emerge from their concealment. A Bug always avoids the light, if possible; and takes advantage of every chink and cranny to make a secure lodgment; its motion is slow and unwieldy; but its sight is so exquisite, that although it persecutes its victim with unceasing assiduity in the dark, the moment it perceives the light, it generally makes good its retreat.—The Rev. Leonard Jenyns has described two or three other species found in this country. [See CIMEX.]

BULIMUS. The name of a very extensive genus of terrestrial molluscs, very much resembling the *Helix*. Some attain to great size. [See *HELIX*.]

BULL-DOG. (*Canis [domesticus] molossus*). A variety of the Dog, remarkable for its short, broad muzzle, and the projection of its lower jaw. The head is massive and large, and the frontal sinuses large; the lips are thick and pendulous; the ears pendant at the extremity; the neck robust and short; and the legs short and thick. Though inoffensive and harmless when properly domesticated, the Bull-dog presents to the eye a most terrific appearance: the doubtful and designing leer, the tiger-like shortness of the head, the under-hung jaw, the width of the skull, the distension of the nostrils, and the almost constant sight of the teeth, hold forth a very formidable proof of the power he can exert, when that power is angrily brought into action. The breed is by no means so numerous as formerly, in consequence of the abolition of the barbarous sport of bull-baiting; the butchers, however, use Bull-dogs in catching and throwing down cattle; and it is surprising to see the apparent ease with which the dog will seize an ox by the nose, and hold him perfectly still, or throw him on his side, at his master's command. They become very vicious, and sometimes extremely dangerous, as they advance in years, inflicting dreadful bites for the slightest provocation; in their unrestrained state, indeed, they are a real nuisance, and therefore ought never to be allowed their full liberty. [See Dog.]

BULLA. A genus of Molluscous animals with univalve shells; whose general characters are, that the shell is sub-oval, that the aperture is oblong and smooth, and that one end is a little convoluted. The animal breathes by gills, but has no respiratory tube,

and consequently the margin of the aperture of the shell is entire, or without a fissure or canal. There are numerous species, widely diffused; generally about the size of a bean, tho' sometimes much larger. Most of this genus, especially of the larger sizes, are furnished with an organ exactly resembling the gizzard of a fowl, and which they appear to use for the purpose of masticating their food.

BULLFINCH. (*Loxia pyrrhula* of Linnaeus.) A well-known and pretty bird, about the size of a sparrow. Its wild note is a soft low twitter; but, when tamed, it becomes remarkably docile, and learns with great facility to whistle musical airs, which, if properly taught, it seldom wholly forgets. The bill is strong, short, black, and thick; the upper part of the beak, the ring round the bill, and the origin of the neck, fine glossy black; the back ash grey; breast and belly red; wings and tail black; the upper tail coverts and vent are white; legs dark brown. The female is very like the male, but the colours are less bright, and the under parts of a reddish brown. These birds are common in every part of our island, as well as in most parts of Europe; their usual haunts during summer are woods and thickets; they also frequent our orchards and gardens in the spring, seeking not only the insects which are lodged in the tender buds of fruit-trees, but feeding on the buds; on which account they are regarded by gardeners as among the most pernicious of the feathered race.

BULLFINCH.—(PYRRHULA PYRRHULA.)

The Bullfinch is a native of England, and also of most parts of the European continent. It generally constructs its nest, which is composed of small dry twigs, in the thickest parts of a white or black thorn hedge. The female lays about four or five bluish-white eggs, marked with dark spots at the larger end; and breeds about the latter end of May. The bird is very common in the mountainous parts of Germany; from which

country the market for piping-bullfinches is principally supplied. Other species are met with in Asia, Africa, and America; but they hardly require a distinct notice here. By many naturalists they are made to constitute a separate genus, called *Pyrrhula*, after the type which we have just described.

BULL-FROG. [See Fa00.]

BULL-HEAD, or MILLER'S-THUMB. (*Cottus gobio*.) There are several species of fish, inhabiting different climates, which are denominated Bullheads; but it is the well-known *River Bullhead*, or *Miller's Thumb*, an Acanthopterygious fish, which we are now about to describe. This species is found in clear brooks and rivers, in most parts of

RIVER BULLHEAD—(COTTUS GOBIO.)

Europe. It is only four or five inches long; the head is of a roundish shape, large, broad, and depressed; the gill-fins are round, and beautifully notched at their circumference; and the rays of all the fins are prettily spotted. The mouth is large, and full of small teeth; the general colour of the body is a dark brownish black; the sides lighter, with small black spots; and the under surface of the head and belly white. It is so remarkably stupid, that whatever number may be together, the most inexperienced angler may catch them all. It is generally found among loose stones, under which, from the peculiarly flattened form of its head, it is enabled to thrust itself, and thus to find a hiding place. Mr. Yarrell, in his truly national work "*The British Fishes*," (the wood-cut illustrations of which are such models of excellency,) so amusingly accounts for the popular names of this fish, that we take the liberty of borrowing his words:—"As the term Bullhead is considered to refer to the large size of the head, so the name of Miller's Thumb given to this species, it has been said, is suggested by, and intended to have reference to, the particular form of the same part. The head of the fish, it will be observed, is smooth, broad, and rounded, and is said to resemble exactly the form of the thumb of a miller, as produced by a peculiar and constant action of the muscles in the exercise of a particular and most important part of his occupation. It is well known that all the science and tact of a miller is directed so as to regulate the machinery of his mill, that the meal produced shall be of the most valuable description that the operation of grinding will permit when performed under the most ad-

vantageous circumstances. His profit or his loss, even his fortune or his ruin, depend upon the exact adjustment of all the various parts of the machinery in operation. The miller's ear is constantly directed to the note made by the running-stone in its circular course over the bed-stone, the exact parallelism of their two surfaces, indicated by a particular sound, being a matter of the first consequence: and his hand is as constantly placed under the meal-spout, to ascertain by actual contact the character and qualities of the meal produced. The thumb by a particular movement spreads the sample over the fingers; the thumb is the gauge of the value of the produce, and hence has arisen the sayings of "Worth a miller's thumb;" and "An honest miller hath a golden thumb;" in reference to the amount of the profit that is the reward of his skill. By this incessant action of the miller's thumb, a peculiarity in its form is produced, which is said to resemble exactly the shape of the head of the fish constantly found in the mill-stream, and has obtained for it the name of the Miller's Thumb, which occurs in the comedy of "Wit at several Weapons," by Beaumont and Fletcher, act v. scene 1.; and also in Merrett's "Pinax." Although the improved machinery of the present time has diminished the necessity for the miller's skill in the mechanical department, the thumb is still constantly resorted to as the best test for the quality of the flour."

The ARMED BULLHEAD, or FOGGE, (*Cottus aspilophorus*), is found in the Baltic and Northern seas, and is also taken on the British coasts. It seldom exceeds six inches in length; small crustaceous animals and aquatic insects are its food; and its flesh is said to be firm and good. The head is large, bony, and very rugged; the end of the nose is armed with four short upright spines; and the chin is furnished with several minute cirri. The mouth is small, as are the teeth, which are very numerous. The body is divided longitudinally by eight scaly ridges, and is defended by eight rows of strong scaly plates, of which the elevated ridges form the central lines. The pectoral fins are large, with a broad bar of brown across the centre; the general colour of the upper surface of the body brown, with four broad dark brown bands; tail brown; and the under parts of the body nearly white.

The SIX-HORNED BULLHEAD (*Cottus hexacornis*) is a North American species, about seven inches long. The head is large and depressed, and on it are six nail-shaped processes standing erect; the eyes are large; the mouth is capacious, its margins formed by the intermaxillaries and lower jaw; both jaws and the vomer are set with bands of fine teeth; the gill-covers are composed of several bones connected by membrane, and armed on their exterior edges with four or five small spinous teeth: the bones which support the pectoral fins are also armed with small spines, and have sharp rough edges. The body is much narrower than the head, and tapers to the insertion of the caudal fin. The upper aspect of this fish

presents a clouded admixture of brown and olive-green tints; the belly white; and the fins streaked with bluish-black. This species is said to be extremely tenacious of life; for, after being drawn from the water, they will leap vigorously over the sands, and inflate the head when touched. In this operation the *hrauchiostrongous* membrane is distended, and the several pieces composing the gill-covers are separated by the extension of the intervening membranes. Capt. Sir J. C. Ross, who considers it to be the same with the *Cottus scorpioides* of Fabricius, says that, although very abundant on the Greenland coast, it is more rare in the higher latitudes, but several were taken on both sides of the peninsula of Boothia. The natives prize it highly as an article of food, preferring it to eel-fish or salmon.

BUNTING. (*Emberiza*.) The Buntings form a very interesting group of Passerine birds. The general characters of the family are, that the bill is strong and conic, the upper mandible with a strong knob on the "palate," the sides of each mandible bending inwards; they live principally on seeds, for the breaking of which their bill is well adapted. We select a few from among the numerous species as examples.

The COMMON BUNTING. (*Emberiza miliaria*.) The length of this bird is about seven inches and a half; beak brown; head and upper parts light brown, inclining to olive; under parts yellowish white; quills dusky with lighter edges; upper coverts tipped with white; tail slightly forked and dusky; and legs pale brown. These birds

COMMON BUNTING.—(*EMBERIZA MILIARIA*.)

are common in England, delighting in those parts that abound in corn, and rarely found in uncultivated places: in winter they assemble in vast flocks; and are often taken in nets, and brought to market, where they are sold for larks, but may be easily distinguished by the knob in the roof of the mouth. The female builds her nest on a tuft of dead plants, a few inches from the ground: it is composed externally of grass and a few long hairs. She lays five or six dirty-white eggs, spotted with reddish brown and ash colour.

The BLACK-HEADED, or REED-BUNTING. (*Emberiza schœniclus*.) Birds of this species frequent fens and marshy places, where there is abundance of rushes, among which they nestle. The head, throat, fore part of the neck, and breast, are black; divided by a white line from each corner of the bill, passing downwards and nearly encircling the neck: upper parts of the body and wings reddish brown, each feather with a black streak down the middle; under parts

REED BUNTING.
(*EMBERIZA SCHœNICLUS*.)

white, with brownish streaks on the sides; quills dusky, edged with brown; two middle tail-feathers black, the outer ones almost white; legs and feet dusky brown. The head of the female is rust-coloured, spotted with black; it is destitute of the white ring round the neck, but in other respects it resembles the male. This bird was formerly supposed to suspend its nest between four reeds within a few feet of the water; this, however, is not the case, as it generally places it on the ground at a little distance from the water, and occasionally in a bush, in high grass, or in furze, at a great distance from any water: it is composed of stalks of grass, moss, and fibres, lined with fine grass. The eggs are four or five in number, of a dirty bluish white, with many dark-coloured spots and veins.

To the Bunting Family, but by naturalists placed in different genera from the preceding, belong the three following species:—

The SNOW BUNTING. (*Plectrophanes nivalis*.) This hardy bird is an inhabitant of the mountains of Spitzbergen, Greenland, Lapland, Hudson's Bay, and other cold northern countries: in the Highlands of Scotland (where it is known by the name of the Snow-flake) it is said also to be extremely abundant, and is supposed to be the harbinger of severe weather; which drives it from its usual haunts. The Snow Bunting weighs only about an ounce and a half. The bill and legs are black; the forehead and crown are white, with some mixture of black on the hind part of the head; the back is wholly black; the rump is white; the quill-feathers are black, with white bases; and the secondaries are white, with black spots on their interior webs. The inner feathers of the

tail are black, the three exterior ones being white, with dusky spots near their ends; and from the chin to the tail is of a delicate white. The claw of the hind toe is very long.

SNOW-BUNTING.
(PLECTROPHANES NIVALIS.)

The nest of this bird is said to be placed in the fissures of the mountain rocks, and to be composed of grass, with a layer of feathers inside, and another of the soft fur of the Arctic Fox within that. The female lays five reddish-white eggs, spotted with brown; on its first arrival in this country it is very lean, but quickly grows fat, and is then excellent eating. It sings very sweetly, sitting on the ground; and does not perch, but runs about like the lark, which at first sight it much resembles.

PAINTED BUNTING. (*Emberiza ciris*.) A beautiful bird, of the size of a hedge-sparrow, which inhabits various parts of South America: it builds its nest in the orange trees, and will feed on millet, sucory, and other seeds. It has a very soft and delicate note; and will live in confinement eight or ten years. The head and neck are of a violet colour; upper part of the back and scapulars yellow-green; lower part and all the under side red; wing coverts and tail of an olive-green, tinged with brown, and edged with red. They seldom obtain their full plumage till the third year, so that they are rarely found quite alike.

THE ORANGE-SHOULDERED BUNTING. (*Vidua longicauda*.) This bird, which inhabits the Cape of Good Hope, is the size of a song-thrush; bill strong and dusky, the nostrils almost hid in the feathers; plumage above and below glossy black; lesser wing-coverts crimson, below which is a white spot. The tail consists of twelve feathers, hanging sideways; the two middle ones fifteen inches in length, the rest shortening by degrees, and the outer ones very short; the legs large and brown; claws long and hooked. Of this species M. Vaillant relates some particulars not unworthy of notice in this place. "The female of this beautiful bird," says he, "has the simple colours of the sky-lark, and a short horizontal tail, like that of almost all other birds; the male, on the contrary, is wholly black, except at the shoulder of the wing, where there is a large red patch; and his tail is long, ample,

and vertical, like that of the common cock. But this brilliant plumage and fine vertical tail subsist only during the season of love, which continues six months. This period over, he lays aside his splendid habiliments, and assumes the more modest dress of his mate. The most extraordinary circumstance is, that the vertical tail also changes to a horizontal one, and the male so exactly resembles the female, that it is not possible to distinguish them from each other. The female has her turn. When she reaches a certain age, and has lost the faculty of propagating the species, she clothes herself for the remainder of her days in the garb which the male had temporarily assumed; her tail, like his at that period, grows long, and like his also, from horizontal becomes vertical. The birds of this species associate together, live in a sort of republic, and build their nests near to each other. The society usually consists of about fourscore females; but whether, by a particular law of nature, more females are produced than males, or for any other reason of which I am ignorant, there are never more than twelve or fifteen males to this number of females, who have them in common." The truth is, that the male, except at the breeding season, when the long-tailed feathers are produced, very nearly resembles the female, and may often be mistaken for it by an inattentive observer.

According to our author, this transmutation is by no means confined to this peculiar species of Bunting. Many females of the feathered creation, when they grow so old as to cease laying eggs, assume the more splendid colours of the male, which they retain during the remainder of their lives.

BUPALUS. A genus of Lepidopterous insects, of which there are many species. The *Bupalus pinarius*, called the Bordered White Moth, may be taken as an example. Its wings on the upper side are of a dusky brown colour, and adorned with numerous pale yellow spots. The Caterpillar is green, with a white stripe down the middle of the back, and two stripes on each side of it.

BUPHAGA. There is but one bird which constitutes this genus of Passerine Conirostres, and that is the **AFRICAN OX-PECKER** (*Euphaga Africana*). It is said to be frequently found in Senegal, and that its chief food consists in the larvae of *aspid*, or bot-flies, which it sedulously extracts from the backs of cattle: hence its name. It measures about eight inches and a half in length; is rufous brown above, and of a dull yellowish white beneath. The bill is nearly an inch long, yellowish, with a red tip; the legs and claws are brown. It is extremely wild or shy, and is usually seen in small flocks of six or eight together.

BUPRESTIS: BUPRESTIDÆ. A genus and family of Coleopterous insects, of the family *Serricornes*, distinguished by the toothed or serrated form of the antennæ, and the splendour of its colours; many of its species having spots of golden hue upon an emerald ground, whilst in others azure glitters upon the gold. The subjoined figure

shows one of the curious Brazilian species; it is named *B. penicillata* from the pencils of hairs at the tips and the sides of its elytra. The largest and most brilliant of these beetles

BUPRESTIS PENICILLATA.

are found chiefly in tropical climates. Some of them live for very many years in the larva state. A gentleman in the city of London had a desk that had been brought from India, in which was one of the grubs belonging to this species; several years afterwards the perfect insect made its appearance, and thereby put an end to many surmises of the merchant and his clerks as to certain scratchings which they had long heard in silent wonder.

The Buprestians are hard-shelled beetles, often brilliantly coloured, of an elliptical or oblong-oval form, obtuse before, tapering behind, and broader than thick, so that when cut in two transversely, the section is oval; the legs are rather short, and the feet are formed for standing firmly, rather than for rapid motion; the soles being composed of four rather wide joints, covered with little spongy cushions beneath, and terminated by a fifth joint, which is armed with two claws. In the greater number of coleopterous insects the scutellum is quite conspicuous, but in the Buprestidæ it is generally very small, and sometimes hardly perceptible. These beetles are frequently seen on the trunks and limbs of trees basking in the sun. They walk slowly, and, at the approach of danger, fold up their legs and antennæ and fall to the ground. Being furnished with ample wings, their flight is swift and attended with a whizzing noise. They keep concealed in the night, and are in motion only during the day.

The larvæ are wood-eaters or borers; and both fruit and forest trees are very subject to their attacks. In the tropical parts of S. America the grub of the *Buprestis gigas*, the perfect insect of which is figured in next column, must be exceedingly destructive. They are in general of a yellowish white colour, very long, narrow, and depressed in form, but abruptly widened near the anterior extremity: the upper jaws are provided with three teeth, and are of a black colour; and the antennæ are very short. There are no legs, nor any organs which can serve as such, except two small warts on the under side of the second segment from the thorax. The motion of the grub appears to be effected by the alternate contractions and elongations of the segments, aided, perhaps, by the tubercular extremity of the body, and by its jaws, with which it takes hold of the sides of its burrow, and

thus draws itself along. These grubs are found under the bark and in the solid wood of trees, and sometimes in great numbers. They frequently rest with the body bent sideways, so that the head and tail approach each other; those found under bark usually assuming this posture. The pupa bears a near resemblance to the perfect insect, but is entirely white, until near the time of its last transformation. Its situation is immediately under the bark, the head being directed outwards, so that when the pupa-coat is cast off, the beetle has merely a thin covering of bark to perforate before making its escape from the tree. The form of this perforation is oval, as is also a transverse section of the burrow, that shape being best adapted to the form, motion, and egress of the insect.

BUPRESTIS GIGAS.

Some of these beetles are known to eat leaves and flowers, and of this nature is probably the food of all of them. The injury they may thus commit is not very apparent, and cannot bear any comparison with the extensive ravages of their larvæ. The solid trunks and limbs of sound and vigorous trees are often bored through in various directions by these insects, which, during a long-continued life, derive their only nourishment from the woody fragments they devour. Pines and firs seem particularly subject to their attacks; but other forest-trees do not escape, and even fruit trees are frequently injured by them. We may here remark, that woodpeckers are much more successful in discovering the retreats of these borers, and in dragging out the defenceless culprits from their burrows, than the most skillful gardener or nurseryman.

The wild cherry-tree (*Prunus serotina*), and also the garden cherry and peach trees, suffer severely from the attacks of borers, which are transformed to the beetles called *Buprestis divaricata*, because the wing-covers divaricate or spread apart a little at the tips. These beetles are copper-coloured, sometimes brassy above, and thickly covered with little punctures; the thorax is slightly furrowed in the middle; the wing-covers are marked with numerous fine irregular impressed lines and small oblong square elevated black spots; they taper very much behind, and the long and narrow tips are blunt-pointed: the middle of the breast is

furrowed; and the males have a little tooth on the under-side of the shanks of the intermediate legs. They measure from seven to nine teeth of an inch. These beetles may be found sunning themselves upon the limbs of cherry and peach trees during the months of June, July, and August.

Buprestis dentipes, so named from the denudation on the under-side of the thick fore legs, inhabits the trunks of oak-trees. It completes its transformations and comes out of the trees between the end of May and the 1st of July. It is oblong-oval and flattened, of a bronzed brownish or purplish black colour above, copper-coloured beneath, and rough like shagreen with numerous punctures; on each wing-cover there are three irregular smooth elevated lines, which are divided and interrupted by large thickly punctured impressed spots, two of which are oblique; the tips are rounded. Length rather more than half an inch.

Buprestis Harrisii is a small and broad beetle, of an entirely brilliant blue-green colour, except the sides of the thorax, and the thighs, which, in the male, are copper-coloured: it measures little more than three tenths of an inch in length. The larvæ inhabit the small limbs of the white pine, and young sapling trees of the same kind.

Buprestis Mariana, a species found in the south parts of Europe, is placed along with a closely allied one from America, and two or three other species in the genus *Chalcophora*.

BUPRESTIS MARIANA.

Dr. W. Harris, of Massachusetts, speaking of the great difficulty there is in discovering and dislodging the various grubs of tree-boring beetles, observes:—"When trees are found to be very much infested by them, and are going to decay in consequence of the ravages of these borers, it will be better to cut them down and burn them immediately, than to suffer them to stand until the borers have completed their transformations and made their escape." It is from Dr. Harris's able work on the Insects of Massachusetts that we have derived much of the information in this article.

BURBOT. (*Gadus lota*.) A fish belonging to the order *Malacopterygii*; very highly esteemed for its superior delicacy, and bearing some resemblance to the eel in its body, except that it is shorter and thicker. The head is broad and flat; the eyes small and lateral; the mouth wide; the jaws

armed with several rows of sharp teeth; the lower jaw furnished with a beard of considerable length, and two small cirri seated on the top of the nose. The colour of the Burbot varies; some being dusky, and others of a dull green, spotted with black, and often with yellow: the belly is some is white; and the skin is remarkably smooth

BURBOT. — (*GADUS LOTA*.)

and slippery. The first dorsal fin is short, and the second is placed immediately behind it, extending almost to the tail; the vent is situated near the centre of the belly; the anal fin reaches almost to the tail; and the tail is rather short and rounded. The Burbot is found in several of the English rivers and lakes of the northern countries; but it is said to arrive at its greatest perfection in the lake of Geneva, where it sometimes weighs six pounds, though in this country it seldom exceeds two or three.

BURSATELLA. A genus of marine Mollusca, without shells, found in the Indian seas.

BUSTARDS. (*Otis*; *Otidæ*.) A genus and family of Cursorial Birds, distinguished for their powers of running and their shyness: some of the Asiatic species, such as the *Floricorn*, are much sought for by the Indian sportsman as a delicacy for the table. We here mean to confine our attention to the two species indigenous to the British Islands, although now both are very rare birds.

The **GREAT BUSTARD** (*Otis tarda*) is the largest of European land birds, the male being about four feet long, and measuring nine feet from tip to tip of the wings when extended, while its weight is on an average twenty-five pounds. The head and neck are ash-coloured, and there is a tuft of feathers about five inches long on each side of the lower mandible. The hack is transversely barred with black and bright ferruginous colours, and the primaries are black. The tail consists of twenty feathers, broadly barred with red and black; and the legs are naked, dusky, and without a hind toe. The female is not much more than half the size of the male, and has the crown of the head of a deep orange colour, traversed by red lines; the remainder of the head is brown; her colours are not so bright as the male, and she has no tuft on each side of the head. There is likewise another very essential difference between the male and the female; the former being furnished with a sack or pouch, situated in the fore part of the neck, and capable of containing nearly two quarts: the entrance to it is immediately under the tongue. This singular reservoir the bird is supposed to fill with water, as a supply in the midst of those dreary plains where it is accustomed to wander; it is also

said to make use of it when attacked by birds of prey, by so violently ejecting it as to baffle their attacks. These birds were formerly seen in considerable flocks on the extensive plains of Wiltshire, Dorsetshire, and in parts of Yorkshire; but as cultivation has advanced, they are become very scarce. They are very shy and vigilant, and

GREAT BUSTARD. — (OTIS TARDA.)

by no means easy to shoot: they run with great speed, and aid their course with their wings, like the ostrich. They feed on grain, seed, worms, &c.; make their nest by merely scraping a hole in the earth; and lay two eggs, as large as those of a goose, of a pale olive tint, with dark spots. They seldom wander far from their accustomed haunts, and have a great unwillingness to rise on the wing; but when once in the air, they can fly several miles without resting.

THE LITTLE BUSTARD. (*Otis tetrax*.) This bird is very uncommon in England, but in France it is taken in nets, like the partridge. It is a very shy and cunning bird; if disturbed, it flies two or three hundred paces, not far from the ground, and then runs away much faster than any one can follow on foot. The female lays three or four eggs, of a glossy green colour, in June; and as soon as they are hatched, she leads them about as a hen does her chickens. The length of this bird is seventeen inches: the bill is pale brown; irides red; the top of the head black, spotted with pale rusty; the sides of the head, chin, and throat, reddish with black spots: the whole neck in the male is black, encircled with an irregular band of white near the top and bottom; the back and wings rufous and brown, crossed with fine irregular black lines: the under parts of the body, and outer edges of the wings, are white; the tail tawny and white, with black bands: legs grey. The *thick-kneed Plover* is sometimes also locally named "Bustard," but belongs to another order, the Gallatorial Birds. [See (EDICNEMUS).]

BUTCHER-BIRD. [See SHRIKE.]

BUTEO. [See BUZZARD.]

BUTTERFLY. (*Papilio*.) The popular English name of an extensive group of beautiful insects, belonging to the order *Lepidoptera*, as they appear in their fully developed state. They are distinguished from other insects by these general characters: their antennae are clubbed at the extremities; their wings, when at rest, are closed together over their backs; and they fly only in the day-time. Butterflies are also distinguished from the other *Lepidoptera* by the superior brilliancy of their colouring, and by the beauty of the under as well as the upper side of the wings. "The Butterfly," as Mr. Knapp observes, "light, airy, joyous, replete with life, sports in the sunshine, wantons on the flower, and trips from bloom to bloom, gay as the brilliant morn, and cheerful as the splendour of heaven: heat and light appear to be the very principle of his being; in a cloudy or a chilly atmosphere his energies become suspended, and, closing his wings, he reposes like a sickly thing upon some drooping flower: but let the cloud disperse, the sun break out, he springs again to active life; associating with the birds of day, and denizen of the same scenes, he only seems of a less elevated order."

Butterflies are very careful in depositing their eggs in places where they are likely to be hatched with the greatest safety and success. They lie dormant through the winter; but when the sun calls forth vegetation, and vivifies the various eggs of insects, caterpillars are seen on various plants, eating their leaves, and preparing for a state of greater perfection. Their form is long and cylindrical, and they consist of thirteen segments, including the head; they have eight feet, and nine spiracles on each side. Those feet which are attached in pairs to the first three segments of the trunk inclose the parts which are developed into the permanent legs of the future Butterfly; the remaining five pairs of feet are membranous, short, and thick, and are finally lost with the moultings of the skin.

The external form of the chrysalids varies according to the species of Butterfly that inhabits them; in all, however, there are apertures opposite to the thorax, by which respiration is carried on during the whole period of their inactive state. After the appointed time, when the creature has acquired sufficient vigour, the shell is broken, which at once constituted "the grave of the caterpillar and the cradle of the butterfly;" the down already grown upon the insect has completely separated it on all sides from the shell, which by the action of the head is broken opposite to that part, and affords free egress to the prisoner it so long confined. The wings of the Butterfly, on its first appearance, are closely folded; but by the help of a fluid constantly circulating through them, they are soon expanded, and sufficiently hardened, by the action of the air, to endure the efforts of flying. It is then that the insect enters upon a more enlarged sphere of action, with increased powers: he ranges from flower to flower, darting his rostrum into their nectaries for the delicious stores they contain. Then, too, in the full

possession of every faculty granted to his race, he prepares to multiply and perpetuate it.

This last and most considerable metamorphosis is attended with a greater change in the economy of the insect than of the preceding; for not only the skin, but the teeth, jaws, and even the cranium, are left behind. The work of Herold, on the transformation of the Cabbage Butterfly, may be judiciously consulted by the student; while Lyonet's researches and great book on the caterpillar of the Goat Moth, teach many particulars of the transformation of a large moth. There is a paper on the wings of *Lepidoptera* by Bernard Deschamps well worth the attention of persons fond of the microscope (see "Annales des Sciences Naturelles," 2od ser., t. III. 1835). The quantity of food taken by them in their last state is comparatively small to what they antecedently devoured. For a short time after their appearance on the wing, they discharge some drops of a red-coloured fluid; but its appearance on the surface of the earth has at different times been regarded, by vulgar superstition, as drops of blood fallen from the clouds, and was presumed to be portentous of some heavy calamity.

Various insects prey upon the Butterfly, or hasten the approach of its dissolution. Many species of Ichneumonidæ perforate the body of the insect while a caterpillar, and there deposits its eggs; and although the caterpillar continues to live, and is transformed into a chrysalid, no Butterfly is produced from it, those internal parts that were essential to its perfection being consumed by the larvæ of the ichneumon. From the great fecundity and variety of the insects of this genus, they probably would soon cover the earth, did not nature provide a bar to their increase by multiplying their enemies: hence they are destined to become the food of a great number of animals of various kinds, some of which swallow them entire, others macerate their bodies; while many accomplish their destruction by gradually sucking their juices. It has been calculated that a single pair of sparrows, in order to supply themselves and their young, may destroy three thousand three hundred and sixty Butterflies in one week.

"The clothing of the organs of flight in the Butterfly excites the admiration of the most incurious beholder. The gorgeous wings of these universal favourites owe their beauty to an infinite number of little plumes, thickly planted in their surfaces, and so minute as to seem like powder; but which are in fact an innumerable number of small scales, varying in shape and length in different species, and discoverable only by the assistance of a microscope.

"The Butterfly requires no other food than the nectareous juices which are distilled from flowers, or the saccharine substance which exudes from the leaves of vegetables; it will sometimes alight and suck the sweets of ripe fruit that has been broken by its fall. The skies are its proper habitation—the air is its element; the pageantry of princes cannot equal the ornaments with which it is

invested, or the rich colouring that embellishes its wings. There is nothing in the animal creation so beautiful or splendid as many species of these insects; they serve to banish solitude from our walks, and to fill up our idle intervals with the most pleasing speculations.

"Butterflies fly generally only in the day. They accompany the sun in his course, and before he sets disappear. With us, says Mr. Samouelle, many of the species are extremely local; and, from the shortness of their lives, require greater assiduity in the collector, and a wider range of search, than is generally supposed. As an illustration of this fact, we must observe that the number of *Papilionidæ* found in England is about seventy-two. Of this number not more than fifty are to be met with within twenty-five miles of London; and of these several are confined to the vicinity of a chalk-cliff, or are peculiar to a meadow or a certain wood. Even in these situations their appearance in the perfect state is limited but to a few days and at a certain season of the year. Of the remaining number, not found within this distance from London, some are confined to fens, nearly a hundred miles distant from the metropolis, and others to the mountains of Scotland; but they are allegedly limited in the times of their appearance and the shortness of their lives. There is also another circumstance in the history of these insects, which must not be passed over in silence; and that is, there are several species which, from some hitherto unknown cause, appear in the proper season, but in certain years only, when they will be found in abundance, and probably extended over a vast tract of the country. These, however, disappear, and not a single specimen is to be found for a period of many years, when they will again be seen as plentiful as before. This is a circumstance that is not confined to England, where it might be attributed to our ever-varying climate, but occurs also in tropical countries."—*Bull. Coll. Vade Mecum*.

"If you denude the wings of any Butterfly, which you may easily do by scraping it lightly on both sides with a penknife," as Messrs. Kirby and Spence observe, "you will be amused to trace the lines in which the scales were planted, consisting of innumerable minute dots: the lines of the under side, in some cases, so cut those of the upper side, as by their intersection to form lozenges. With regard to the position of the scales on the wing, they usually lie flat, but sometimes their extremity is incurved. But though the general clothing of the wings of *Lepidoptera* consists of these little scales, yet in some cases they are either replaced by hairs or mixed with them. Thus, in the clear parts of the wings of *Heliconians*, *Attiæ*, &c., short inconspicuous hairs are planted; in a large number of the Orders the upper side of the anal area of the secondary wings is hairy; in several *Crepusculars*, where there is a double layer, as before mentioned, the upper one consists of dense hairs, except at the apex, and the lower one of scales; and in most of them the scales of the primary wings are piliform, and the secondary

are covered by what approach very nearly to real hairs."

The number of exotic Butterflies is very great both in orders and in genera; and students are referred [we limit ourselves to British books] to Dr. Horsfield's elaborate work on those of Java, but especially to the truly admirable work on the Genera of Diurnal Lepidoptera, by Edward Doubleday, F.L.S., illustrated by William Hewitson, and continued by Mr. Westwood since Mr. Doubleday's death. Our space prevents us from even alluding to the numerous genera of those gorgeous insects detailed in this splendid book. It is, however, but bare justice to say that a more beautiful work has rarely been published. We can also heartily recommend Humphrey's British Butterflies, partly edited by Mr. Westwood, and also the more recently published work of the Rev. F. O. Morris, in a single volume, bearing a similar title: the coloured figures of the latter work are admirably given. Butterflies, by their forms, contrasts of colour, and other peculiarities, not only charm the eye, but have afforded valuable information to artists. The great Van Dyck and our countryman Stothard are known to have been indebted to Butterflies for many fine hints on colour, both in harmony and contrast. In the present work we must confine ourselves to the British Genera as much as possible. [See PAPILIO; PONTIA; MELITÆA; ARGYNNIS; LIMENITIS; VANESSA; APATURA LYCENA; POLYOMMATUS; THECLA; HIPPARCHIA; HESPERIA; PARNASSUS, &c.]

BUZZARD. (*Falco buteo* of Linnæus.) This bird is supposed to be the most common in England of all the hawk tribe. It has a thick heavy body; measures about twenty-two inches in length, and the full expansion of its wings is about fifty. It is usually of a ferruginous brown above, and yellowish white beneath, with large longitudinal spots and dashes: the tail is barred with black and ash-colour; the tip is dusky white. It breeds in extensive woods, generally fixing on the old nest of a crow, which it enlarges, and lines with wool and other soft materials. It lays two or three eggs, which are sometimes wholly white, and at others spotted with yellow; and when the female happens to be killed during the time of incubation, the cock hatches and rears the brood. The young accompany the old birds for some time after quitting the nest; a circumstance unusual in other birds of prey, which always drive off their young as soon as they can fly. The Buzzard is very sluggish and inactive, remaining perched on the same bough for the greatest part of the day, and always found near the same place. It feeds on birds, frogs, insects, moles, and mice. By modern naturalists it is placed in the genus *Buteo*. [For Honey Buzzard, see PERNIS.]

BYRRHUS; BYRRHIDÆ. A genus and family of Coleoptera. The insects belonging to this genus have an ovate body, convex or sub-globular in some species, with the elytra covered by a short pile, and the head is retracted under the thorax. *Byrrhus pilula* is about the size of the common Lady-bird:

its colour is a dull brown, with a few obscure blackish lines down the wing-shells: it is of an extremely convex shape, and, when disturbed, contracts its limbs, and lies in an inert state, like an oval seed or pill, while thus counterfeiting death as a means of escape from danger. It is found on various plants in gardens and elsewhere.

BYSSOARCA. A sub-genus of Molluscous animals, affixed by byssiform filaments to other bodies, a particular muscle being protruded through the gaping part of the shelly valves.

BYSSOMYA. A genus of Acephalous Molluscs, which live in the fissures of rocks, attached by a byssus: sometimes the animal buries itself in the sand or lodges in small stones, &c.

CACHALOT. (*Physeter macrocephalus*.) The Spermaceti Whale; the head of which nearly equals the rest of the body in length, and surpasses it in bulk. It is an object of great commercial importance on account of the oil and spermaceti which it yields. Mr. Beale has published a most admirable and readable work on it. [See WHALE.]

CACILICAME. [See ARMADILLO.]

CACTORNIS. A subgenus of Passerine birds, closely allied to *Geospiza*, but differing from it in the beak being elongated, somewhat like that of a *Quiscalus*, and very sharp-pointed. The typical species is *Cac-*

CLIMBING CACTUS BIRD.
(*Oaotornis scandens*.)

tornis scandens. The male is of a sooty black, the female brownish and spotted. This species was found by Mr. Darwin in the Galapagos; its most favourite resort is the *Opuntia Galapageia*, a species of the Cacti tribe; about the fleshy leaves of which they hop and climb, even with their back downwards, whilst feeding with their sharp beaks,

both on the fruit and flowers. They frequently also alight on the ground and search for seeds on the parched volcanic soil.

CADDICE-WORM, or CAD-BAIT. [See *PHYRGANEA*.]

CÆCILIA. The name of a genus of Serpents, about a foot in length, and having much the appearance of an eel. They are natives of South America, and are said to be innocuous.

CAIMAN. [See *ALLIGATOR*.]

CALANDRA: CALANDRIDÆ. A genus and family of Coleopterous insects, closely allied to the *Curculionidæ*; some of the minute species of which commit great havoc in granaries, both in their larva and perfect state. The species are very numerous, and among them is the well-known Corn-weevil (*Calandra granaria*). This insect bores a hole into the grain with its proboscis, and there deposits an egg, which turns to a little grub, and devours the whole of the inside of the grain, leaving the husk entire. Another species of *Calandra*, distinguished by its having four red spots on its elytra, attacks rice in the same way as the one above mentioned does wheat.

These insects must not be confounded with the still more destructive larvæ of the Corn-moth (*Tinea granella*), which also attack stored grain, nor with the orange-coloured maggots of the Wheat-fly (*Cecidomyia tritici*), which are found in the ears of growing wheat. Although the grain-weevils are not actually injurious to vegetation, yet as the name properly belonging to them has often been misapplied, some remarks upon them here may not be inappropriate.

The true Grain-weevil or Wheat-weevil of Europe (*Calandra granaria*), in its perfect state, is a slender beetle of a pitchy red colour, about one-eighth of an inch long, with a slender snout slightly bent downwards, a coarsely punctured and very long thorax, constituting almost one-half the length of the whole body, and wing-covers that are furrowed, and do not entirely cover the tip of the abdomen. This little insect, both in the beetle and grub state, devours stored wheat and other grain, and often commits much havoc in granaries and brewhouses. Its powers of multiplication are very great, for it is stated that a single pair of these destroyers may produce above six thousand descendants in one year. The female deposits her eggs upon the wheat after it is housed, and the young grubs hatched therefrom immediately burrow into the wheat, each individual occupying alone a single grain, the substance of which it devours, so as often to leave nothing but the hull; and this destruction goes on within, while no external appearance leads to its discovery, and the loss of weight is the only evidence of mischief that has been done to the grain. In due time the grubs undergo their transformations, and come out of the hulls in the beetle state, to lay their eggs for another brood. These insects are effectually destroyed by kiln-drying the wheat; and grain that is kept

cool, well ventilated, and frequently moved, is said to be exempt from attack.

CALAPPA, or BOX CRAB. A genus of Crustacea, belonging to the family *Calappidæ*. They are named by the French *cogs de mer*, from their crested chelæ, which are large, equal, compressed; with their upper edge, which is notched or crested, very much elevated, and fitting exactly to the external border of the shell or carapace, so as to completely cover the mouth and anterior parts: the rest of the feet short and simple; carapace short and convex, forming, behind, a vaulted shield, under which the posterior legs are hidden when the animal is in a state of repose: eyes mounted on short pedicles, and not far apart. There are several species widely diffused: some inhabit the seas of the Indian Archipelago, and of New Holland; others are met

CALAPPA ORISTATA.

with in the Pacific and Atlantic oceans, the seas of South America, &c.; others, again, inhabit the Mediterranean sea. They frequent the fissures of rocks, some of them at a great depth. The females deposit their eggs in summer.

CALATHUS. A genus of Coleopterous insects, belonging to the *Carrabidæ*. Several species are found in the British islands, most frequently under stones and house rubbish.

CALLICHTHYS. A genus of abdominal Males opterygious fishes, family *Siluridæ*. The body and head are protected by large, hard, scaly plates; the mouth is furnished with four long cirri; the teeth are very small; the eyes are also small, and situated on the side of the head. They are natives of South America and other hot climates, where the rivers frequently dry up; and they can not only live for a considerable time out of water, but they are said to perform long journeys over land, directing their course to some other stream.

CALLIDIUM. A genus of Coleopterous insects, belonging to the family *Longicornes*; one species of which (*Callidium bajulus*) in the larva state is particularly destructive to fir timber. This is a flattish rusty black beetle, with some downy whitish spots across the middle of the wing-covers; the thorax is nearly circular, is covered with fine whitish down, and has two elevated polished black points upon it; and the wing covers are very coarsely punctured. It inhabits fir and spruce timber, and may often

Gould, in his very magnificent "Birds of Australia," has figured all the species of this genus; and from his account of the species called *Wy-la* (from its whining call note) by the natives of N. S. Wales, and *Calyptorhynchus funereus* by naturalists, we extract the following observation:—it is usually met with in small companies of from four to eight in number, except during the breeding season, when it is only seen in pairs. Its food is much varied; sometimes the great belts of *Banksia* shrubs are visited, and the seed-covers torn open for the sake of their contents, while at others it searches greedily for the larvæ which are deposited in the wattles and gum trees (*Encalyptus*). Its flight is very heavy, flapping, and laboured; but Mr. Gould informs us that he has sometimes seen it dive between the trees in a most rapid and extraordinary manner. The eggs are white, two in number, and deposited on the rotten wood in the hollow branch of a large gum tree.

CAMBERWELL BEAUTY [BUTTERFLY.] A name given to a species of Butterfly, of the genus *VANESSA* [which see].

CAMEL. (*Camelus*.) A genus of mammiferous ruminating quadrupeds without horns, further distinguished by the possession of incisive, canine, and molar teeth: the up-

CAMEL.—(*CAMELUS BACTRIANUS*)

per lip is divided; the neck long and arched, having one, or two, humps or protuberances upon the back, and naked callosities at the joints of the leg, the lower part of the breast, &c. They have a broad, expanded, elastic foot, terminated in front by two comparatively small hoofs, or toes; the whole structure of it being admirably fitted for enabling the animal to travel with peculiar ease and security over dry, stony, and sandy regions. The native country of this genus is said to extend from Mauritania to China, within a zone of 1000 miles in breadth.

The common Camel (*Camelus Bactrianus*), having two humps, is only found in the northern part of this region, and exclusively from the ancient Bactria, now Turkestan, to China. It is larger than the Dromedary; the limbs are not so long in proportion to the body; the muzzle is larger and more tumid; the hair of a darker brown, and the usual gait slower: but the most obvious distinction is afforded by the Bactrian Camel having two humps, and the Drome-

dary or Arabian Camel having but one, which single hump occupies the middle of the back, rising gradually on all sides towards its apex.

The Arabian, or single-hump Camel (*Camelus dromedarius*) is found throughout the entire length of this zone, on its southern side,

DROMEDARY.—(*CAMELUS DROMEDARIUS*.)

as far as Africa and India. The general height of the Arabian Camel, measured from the top of the dorsal hump to the ground, is about six feet and a half; but from the top of the head when the animal elevates it, not much less than nine feet: the head, however, is generally so carried as to be nearly on a level with the hump, or rather below it, the Camel bending the neck extremely in its general posture. In some particular attitudes, perhaps, the Camel may be said to have an elegant and picturesque appearance, yet its general aspect, and more especially its dorsal hump, at first sight, is apt to impress on the mind the idea of deformity, rather than a truly natural conformation.

It is highly probable that the Camel has long ceased to exist in its wild or natural state, as it has been enslaved by man from the earliest times of which we have record. Unlike the elephant, and other animals which cease to breed in a state of captivity, the Camel is as prolific as if at liberty; and vast numbers are raised and employed throughout the East, especially in the commerce carried on between the people residing in the vicinity of the great deserts. In regions where water is scarce, and wells or springs are several days' journey distant from each other, it would be impossible to traverse the country with the usual beasts of burthen. But the Camel can abstain from drinking for seven or eight days together without injury—an important advantage, which is owing to the possession of an additional cavity in the stomach, destined to receive water, whenever it can be procured, and capable of retaining it unchanged for a long time. "But," as the writer of the zoological articles in Brande's Dictionary observes, "besides a reservoir of water to meet the exigencies of long journeys across the desert, the Dromedary and Camel are provided with a storehouse of solid nutriment, on which they can draw for supplies long after every digestible part has been extracted from the contents of the stomach: this storehouse consists of one or two large collections of fat stored up in ligamentous

cells supported by the spines of the dorsal vertebrae, and forming what are called the humps. When the Camel is in a region of fertility, the hump becomes plump and ex-

PART OF THE SKULL OF DROMEDARY, WITH ITS FOOT VIEWED FROM BENEATH AND FROM ABOVE.

panded; but after a protracted journey in the wilderness it becomes shrivelled and reduced to its ligamentous constituent, in consequence of the absorption of the fat. Buffon carried his telological reasoning, or the ascription of design, so far as to assert that the humps on the backs of the Camel were badges of slavery, and intended to adapt them to the burthens of their task-masters; and he supported this ingenious idea by the unfounded assertion that the dorsal prominences did not belong to the Camels in free nature. But the true uses of the fatty humps, as of the water-cells, relate to the exigencies of the *Camelidae* of the deserts under every condition."

SKELTON OF *CAMELUS DROMEDARIUS*.

Possessing strength and activity surpassing that of most beasts of burthen; docile, patient of hunger and thirst, and contented with small quantities of the coarsest provender, the Camel is one of the most valuable gifts of Providence. There is nothing, however, in the external appearance of the animal to indicate the existence of any of its excellent qualities. In form and proportions, it is very opposite to our usual ideas of perfection and beauty. A stout body, having the back disfigured by one or two humps; limbs long, slender, and seemingly too weak to support the trunk; a long, thin, crooked neck, surmounted by a heavily-proportioned head, are all ill suited to produce favourable impressions. Nevertheless, there is no creature more excellently adapted to its situ-

ation, nor is there one in which more of creative wisdom is displayed in the peculiarities of its organization. To the Arabs and other wanderers of the desert, the Camel is at once wealth, subsistence, and protection. The milk furnishes them with a large part of their nutriment. The flesh of the young animal is one of their greatest luxuries; of the skins they form tents, or manufacture them into saddles, harness, pitchers, shields, and many other articles; the various sorts of hair, or wool, shed by the Camel, are wrought into different fabrics; and its very excrements serve as fuel, or are applied to other useful purposes.

These animals are trained, when extremely young, to the labours which they are afterwards to perform: and with this view, when but a few days old, their limbs are folded under their body, and they are compelled to remain on the ground whilst they are loaded with a weight, which is gradually increased as they increase in strength. The pace of the Camel is a high and swinging trot, which, to persons unaccustomed to it, is at first disagreeable and apparently dangerous, but is afterwards tolerably pleasant and secure. The Arabians in general ride on a saddle that is hollowed in the middle, and has at each bow a piece of wood placed upright, or sometimes horizontally, by which the rider keeps himself in the seat: and the animal is guided, or stopped, by means of a cord that serves as a bridle, and is affixed to a ring which is passed through his nostrils. Small Camels carry from 600 to 800 lbs.; the largest and strongest bear 1000 lbs. or upwards from thirty to thirty-five miles a day; but those which are used for speed alone are capable of travelling from sixty to ninety miles a-day. When a caravan of Camels arrives at a resting, or baiting place, they kneel, and, the cords sustaining the load being untied, the bales slip down on each side. They generally sleep on their bellies, crouching between the bales they have carried; the load is, therefore, replaced with great facility. In an abundant pasture they generally browse as much in an hour as serves them for ruminating all night and for their support during the next day. But it is uncommon to find such pasturage, and they are said to prefer nettles, thistles, cassia, and other prickly vegetables, to the softest herbage.

The female goes with young twelve months, and brings forth one at a birth. Her milk is very rich, abundant, and thick, but of rather a strong taste; though when mixed with water it forms a very nutritive article of diet. Breeding and milk-giving Camels are exempted from service, and fed as well as possible, the value of their milk being greater than that of their labour. The young Camel usually sucks for twelve months; but such as are intended for speed are allowed to suck, and exempted from restraint, for two or three years. The Camel arrives at maturity in about five years, and the duration of its life is from forty to fifty years.

There are several races or varieties both of the Arabian and the Bactrian Camel,

differing, like those of horses, in strength, size, swiftness, and elegance of form. A breed of peculiar swiftness is said to be reared in China; a white variety occurs in some parts of Siberia; and a hybrid or mixed breed is occasionally obtained between the Bactrian and Arabian Camel.

CAMELOPARD and **CAMELOPARDALIS**. [See GIRAFFE.]

CAMELUS. [See CAMEL.]

CAMPAGNOL. A French name sometimes given to the small Rodent animals called *Voles*. [See VOLE.]

CAMPANULARIADÆ. A group of cœlenterate animals, or, more strictly, a family of hydroid polyps, embracing several genera, such as *Campanularia*, *Laomedæa*, and *Cymodocea*, all being zoophytes closely allied to the well-known Sertularias [which see, p. 604]. The Campanularias proper are distinguished by the following characters:—"polypidom, horny, tubular, creeping or erect, plant-like; the main stem giving off branches bearing stalked, campanulate, or bell-shaped cells, the stalks being annulated and either alternately or irregularly dis-

CAMPANULARIA DICHOTOMA

posed." The genus *Campanularia* contains eleven British species, of which one is here represented. They may be reproduced in one, either, or all of the following ways:—*first*, by a simple process of gemination or budding, each bud becoming a stalked polyp; *secondly*, by modified polyps, which bud off or pulvulate in the form of jelly-fishes (Medusoids), these latter having eggs in them which become transformed into polyps; *thirdly*, by polyp-heads which contain eggs, these latter giving off young ciliated embryos or gemmules, which, after swimming about for a time, settle down and grow up into polyps. [See ALTERNATION OF GENERATION in SUPPLEMENT.]

CAMPULA. [See SUPPLEMENT.]

CANARY-BIRD (*Carduelis canaria*.) The Canary-bird, or Canary-finch, as it is sometimes called, is a well-known captive songster in this and most other European countries. It is a native of the Canary Islands, but it has continued so long in a domestic state that its native habits seem almost forgotten. In the wild state the pre-

vailing colour is grey or brown, mingled, however, with other colours, but never reaching the brilliancy of plumage exhibited by the bird in captivity. Dr. Heineken, who describes its character and habits in Madeira, where these birds abound, says, "it builds in thick, bushy, high shrubs and trees, with roots, moss, feathers, hair, &c.; pairs in February; lays from four to six pale blue eggs; and hatches five, and often six times in the season. It is a delightful songster, with, beyond doubt, much of the nightingale's and skylark's, but none of the wood-lark's song." It was brought into Europe early in the 16th century, and is believed to have spread from the coast of Italy, where a vessel, which was bringing to Leghorn a number of these birds besides its merchandise, was wrecked. The climate being favourable, they increased, and would certainly have become naturalized, had they not been rendered scarce by the desire to possess them, as well as from there being few besides male birds brought over.

In their native islands, a region equally celebrated for the beauty of its landscapes and the harmony of its groves, the Canary-birds are of a dusky-grey colour, and so very different from those usually seen in Europe, that some naturalists have even doubted whether they are of the same species. The original stock has undergone so many changes from its being domesticated, from the climate, and from the union with birds analogous to it, that now we have Canaries of all colours. "Those Canaries that have the upper part of the body of a dusky green or linnæa-brown, and the under part the yellowish green of the green-bird, with dark-brown eyes, are the strongest, and most nearly resemble the primitive race. The yellow and white often have red eyes, and are the most tender. The chestnut are the most uncommon, and hold a middle rank for strength and length of life between the two extremes. But as the plumage of the intermediate ones is a mixture of these principal colours, their value depends on the pretty and regular manner in which they are marked. The Canary that is most admired amongst us now is one with the body white or yellow; the head, particularly if crested, wings, and tail, yellowish dun. The second in degree is of a golden yellow, with the head, wings, and tail black, or at least dusky grey. Next follow the grey or blackish, with a yellow head and-collar; and the yellow with a blackish or green tuft; both of which are very much valued. As for those that are irregularly spotted, speckled, or variegated, they are much less sought after, and are used to pair with those of one colour, white, yellow, grey, brown-grey, and the like."

In choosing Canary-birds, those are preferable which appear bold and lively. If their eyes look cheerful and bright, it is a sign of health; but, on the contrary, if they hide their heads under their wings, and gather up their bodies, it is symptomatic of their being disordered. The melody of the song should also be regarded in making a selection; for some will open with the notes of

the nightingale, and, after running through a variety of modulations, end like the titlark; others, again, will begin like the skylark, and, by soft melodious turns, fall into the notes of the nightingale. Lessons may be taught this bird in its domestic state; but its native note is loud, shrill, and piercing.

Canary-birds sometimes breed all the year round; but they most usually begin to pair in April, and to breed in June and August. In Germany and the Tyrol, where the breeding of these songsters forms the occupation of numbers, and from whence the rest of Europe is principally supplied, the apparatus for breeding Canaries is both large and expensive. A large building is erected for them, with a square space at each end, and holes communicating with these spaces. In these outlets are planted such trees as the birds prefer. The bottom is strewed with sand, on which is cast rape-seed, chickweed, and such other food as they like. Throughout the inner compartment, which is kept dark, are placed brooms for the birds to build in, care being taken that the breeding-birds are guarded from the intrusions of the rest. With us, however, the apparatus is much less expensive; a breeding-cage often suffices; and, at most, a small room, without any particular preparation.

CANCELLARIA. A genus of Molluscous animals belonging to the *Entomostomata* of De Blainville. There are many species, most of which are found in the Indian and African

CANCELLARIA OBTUSA.

seas, but many are from the warm latitudes of the Pacific side of S. America. There is a monograph of this genus by G. B. Sowerby, Jun., F.L.S., in the "Conchological Illustrations," with figures and descriptions of all the species then known. To this work we refer our readers, as well as to Mr. Sowerby's "Thesaurus Conchyliorum." The genus derives its name from *cancellatus*, cross-barred; and the shell is characterized as oval or turretted; spire generally short, slightly elevated, and pointed; mouth oval, having either a very short canal or a notch only; the outer lip marked within by transverse ridges; inner lip spread over part of the body whorl, terminating in a straight, thick, obtuse columella, with several irregular plaits. The shells are rare, but not remarkable; and are usually rough to the touch, and striped.

CANCER. The name applied by Linnaeus to nearly all the species of the class Crustacea. It is now restricted by naturalists in this country to the genus of which the

common black-clawed crab (*C. pagurus*) is the type. Other species are found in North America and South America. [See CRAB.]

CANCROMA. [See BOAT-BILL, p. 79.]

CANIS. In the Linnæan system of zoology, a distinct and very large genus of animals of the class *Mammalia*, order *Feræ*, including all the Dog kind. The characters of this genus are,—that the several species (the common dog, the wolf, the jackal, the fox, &c.) have six upper fore-teeth, the lateral ones being longest, and the intermediate ones of a lobated figure; that there are also six fore-teeth in the lower jaw, of which the lateral ones are lobated; that the canine teeth are single and incurved; and that the grinders are six or seven in number. [See DOG.]

CANTHARIDÆ. A family of Coleopterous insects, the species of which are numerous and widely diffused. They differ from each other in their size, shape, and colour: the largest are about an inch long. Some are of a pure azure, others of a pure gold, some of a mixture of gold and azure, and others scarlet; but all are brilliant, and very beautiful.

The **CANTHARIS VESICATORIA**, Spanish Fly, or Blister Beetle, so well known for its medical uses, is the most noted. This insect is about three quarters of an inch in length, and of a beautiful metallic gold green colour, sometimes changing into bluish green: the head is smooth and polished, and in the forehead are two eyes of a green colour; the

"SPANISH FLY," OR BLISTERING BEETLE
(*CANTHARIS VESICATORIA*.)

wing-cases are membranous, convex above and hollow beneath; thin, but strong, and covering the upper part of the body. The abdomen is composed of eight moveable rings, furrowed from end to end; the legs and antennæ are bluish-black. In Spain, Portugal, and Italy these insects are abundant; in France also they are sometimes found; but are rarely seen in this country. They frequent ash trees, and feed upon its leaves; they are also to be met with on the poplar, the rose, the honey-suckle, and some other sweet-scented shrubs. Although, as we have just said, they but rarely occur in this country, yet at the meeting of the Linnæan Society, Nov. 7. 1837, Mr. Newman exhibited a number of specimens, taken during the preceding summer, near Colchester, where they had appeared by millions, stripping the ash-trees of their leaves. When touched they feign death, and emit a highly offensive odour; which, however, is a guide to those whose business it is to catch them. The

most common method of killing them is to expose them to the vapour of hot vinegar: they are then dried on hurdles, and put away in boxes for use.

In Silesia (says Mr. Slater) the *Cantharis vesicatoria* is only a summer guest; it appears there suddenly in June, in rather numerous swarms, which arrive during the night, and are found early in the morning upon the ash, honey-suckle, and some other trees and shrubs, which they soon strip of leaves. Their presence is announced by a most penetrating odour, perceptible at a great distance from the trees on which they sit, and suggesting unpleasant ideas of blistering ointment. Their susceptibility to cold is remarkable; the freshness of early dawn is sufficient to chill and benumb them, and if the trees be then gently agitated, they fall down. In this manner they are collected for sale, and killed by sprinkling with cold water.—(Zoologist.)

In North America, according to Dr. Harris, potato-vines are very much infested by two or three kinds of *Cantharides*, swarms of which attack and destroy the leaves during midsummer. One of these kinds has thereby obtained the name of the *potato-fly*. It is the *Cantharis vittata*, or striped *Cantharis*. It is of a dull tawny yellow or light yellowish red colour above, with two black spots on the head, and two black stripes on the thorax and on each side of the wing-covers. The under-side of the body, the legs, and the antennæ are black, and covered with a greyish-down. It is more than half an inch long; the thorax is much narrowed before; and the wing-covers are long and narrow, and cover the whole of the back. It does much mischief in potato fields and gardens, eating up not only the leaves of the potato, but those of many other vegetables.—Another species, a jet-black *Cantharis* (*Cantharis atrata*), measuring nearly half an inch in length, may be seen, about the middle of August, on the potato-vines, and also on the blossoms and leaves of various kinds of golden-rod.—These insects, and others of a similar kind, may be easily taken by brushing or shaking them from the potato-vines into a broad tin pan, and emptied into a covered pail containing a little water, which, by wetting their wings, prevents their flying out when the pail is uncovered; or they may be caught by gently sweeping the plants ther frequent with a deep muslin bag-net. They are easily killed by throwing them into scalding water for one or two minutes. (*Ins. of Massach.*)

CAPERCAILLIE. The Scotch name for *Tetrao urogallus*. [See GROUSE.]

CAPITOSAURUS. [See SUPPLEMENT.]

CAPRA. [See GOAT.]

CAPRIMULGUS: CAPRIMULGIDÆ. A genus and family of Passerine birds, popularly termed *Moth-hunters* and *Goat-suckers*. Their habits are nocturnal, and they have the same light soft plumage, minutely mottled with grey and brown, that characterizes other night-birds. Their eyes are large; the beak, very deeply cleft, and gene-

rally armed with strong *vibrissæ*, is capable of engulfing the largest insects, which are retained by means of a glutinous saliva; the nostrils, placed at its base, are like small tubes; their wings are lengthened; the feet short, with plumed tarsi, and a membrane connecting the basal portion of the toes: the claw of the middle toe is usually pectinated on its inner edge; and the outer toe has only four phalanges, a conformation extremely rare among birds. They live solitarily, or rather permanently in pairs, and are crepuscular in their time of action, pursuing moths and other nocturnal insects: they deposit their [two] eggs on the bare ground, and have generally singular voices. They bear the same relation to the Swifts that the Owls do to the Hawks; their general anatomy very much resembling that of the Cuckoos. The common European species (*Caprimulgus Europæus*) is remarkable for the loud sound it emits, like the hurr of a spinning-wheel. Among the foreign species, a great number have longer tarsi, adapted for running on the ground; and there are some with an appearance of aigrettes on the head. [See GOAT-SUCKER; STEATORNIS; WHIP-POOR-WILL; EGOTIELES; LYSCORNIS.]

CAPROMYS. A genus of *Rodentia*, different species of which are found in the West India Islands. They are herbivorous, preferring aromatic plants. In their movements they are slow, somewhat like a bear. One of these was described by Oviedo as the *Chemis*, a name said still to be applied to the *Capromys Fournieri*. Two other species, *C. prehensilis* and *C. Poyii*, are described. To this genus probably also belongs the "Musk Cavy," described by some authors as almost as large as a rabbit; the upper part of its body is black, and its belly is perfectly white. It inhabits Martinico, and the other Antilles islands; burrows underground; and smells so strongly of musk, that its retreat may be traced by the perfume.

CAPYBARA. (*Hydrocharus capybara*.) A Rodent animal which has also obtained the name of the Water-hog. It grows to the size of a hog of two years old, and is classed with

CAPYBARA.—(*HYDROCHERUS CAPYBARA*.) the *Caridæ*. It inhabits various parts of S. America, but is most common in Brazil. It feeds not only on various vegetables, and

particularly on sugar-canes, but also on fish; for which purpose it frequents rivers, swimming with the same facility as the otter, and taking its prey in a similar manner. The Capybara is, in general, considered as of a gentle disposition, and, though shy and timid, is readily tamed and made familiar. It has a very large head, and a thick, divided nose, on each side of which are strong and large whiskers; the ears are small and rounded; the eyes large and black; and the upper jaw longer than the lower. The neck is short; the body thick, and covered with short, coarse, brown hair: the legs short, and the feet long. Like the Peccary, the Capybara is destitute of a tail; and, dissimilar to all others of this kind, instead of a cloven hoof, it is in a manner web-footed, and thus adapted for an aquatic life.

"These great Rodents are generally called 'Carpinchos;' they occasionally frequent the islands in the mouth of the Plata, where the water is quite salt, but are far more abundant on the borders of freshwater lakes and rivers. Near Maldonado three or four generally live together. In the day-time they either lie among the aquatic plants, or openly feed on the turf plain. When viewed at a distance, from their manner of walking and colour, they resemble pigs: but when seated on their haunches, and attentively watching any object with one eye, they re-assume the appearance of their congeners, the Cavies. Both the front and side view of their head has quite a ludicrous aspect, from the great depth of their jaw. These animals, at Maldonado, were very tame; by cautiously walking, I approached within three yards of four old ones. As I approached nearer and nearer they frequently made their peculiar noise, which is a low abrupt grunt; not having much actual sound, but rather arising from the sudden expulsion of air: the only noise I know at all like it, is the first hoarse bark of a large dog. Having watched the four from almost within arm's length (and they me) for several minutes, they rushed into the water at full gallop, with the greatest impetuosity, and emitted, at the same time, their bark. After diving a short distance they came again to the surface, but only just showed the upper part of their heads. When the female is swimming in the water and has young ones, they are said to sit on her back."—*Darwin's Journal.*

CARABIDÆ. A very numerous family of Coleopterous insects, containing some of the largest of the carnivorous beetles; many of which are adorned with brilliant metallic colours. The body of these insects is of a very firm consistence, whereby they are enabled to creep about under stones, &c., as well as prevented from falling beneath the power of the insects they attack; most of the species of this family being eminently insectivorous; walking about, in search of their prey, on the surface of the ground, under stones, &c., or beneath the bark of trees, or in the moss growing at their roots. They are accordingly of essential service in keeping down the numbers of noxious insects with which our gardens and pastures

might otherwise be overrun. They are not all, however, exclusively carnivorous; since some of the species generally found in corn-fields are clearly ascertained to feed upon growing grain. Some of the species among the larger Carabidæ exhale a fetid odour, discharging at the same time from the abdomen to a considerable distance a caustic and acrid fluid. Few observations have hitherto been made relative to the larvæ of this family; but those which have been noticed are equally voracious with the perfect insects, and are found in similar situations: they are generally long, with the body of equal breadth throughout. The large work of the Count Dejean is the most complete book yet published on this family. There have been, however, many additions to this family of insects, as to most others. There is a very large collection of them in the British Museum.

CARACARA. A South American Falconidous bird of the genus *Polyborus*. It is of the size of the common kite, and has a tail nine inches long. The beak is black, and hooked; the plumage tawny, with white and yellow specks; the feet are yellow, with semicircular, long, sharp, black talons. In its food the Caracara seems to be content with any animal substance: carrion, reptiles, toads, snails, birds, insects, &c.; whatever, in short, will suit the appetite of other ignoble birds of prey, will content the Caracara. It is by no means shy; and though it ventures to approach inhabited places, it is seldom attacked, as it rarely molests domestic poultry. It builds its nest on the tops of trees where the foliage is close, or in a bushy thicket. It lays two eggs, pointed at one end, and spotted with crimson on a reddish-brown ground.

CARCAJOU. [See BADGER.]

CARACAL. (*Felis caracal*.) This animal, called also the Persian Lynx, is a native both of Asia and Africa. It is about the size of a fox; possesses great strength and fierceness; and is used not only in the chase of the smaller quadrupeds, but of the

CARACAL — FELIS CARACAL I

larger kinds of birds, such as herons, cranes, pelicans, &c., which it is said to surprise with great address. When it has seized its prey, it lies motionless for some time upon it, holding it in its mouth. Its colour is a pale reddish-brown, whitish beneath: the ears head is small, the face rather long, the ears sharp and slender, of a dark colour, and terminated by a tuft or pencil of long black hairs.

CARCHARIAS. A genus of Chondropterygious fishes, notorious for their bold and predaceous habits, and distinguished by their trenchant-pointed teeth. [See SHARKS, p. 165; and CARCHARODON in SUPPLEMENT.]

CARDIACEÆ. The cockles and their allies; the shells of which are all equivale, or nearly so. They are furnished with a regularly-toothed hinge, often of great complexity and beauty; and there is always a double abductor muscle: the respiratory orifices are usually prolonged into tubes, which can, however, be drawn within the shell by means of a retractor muscle. There are numerous species, widely diffused; many of them being remarkable for the smallness and delicacy of their shells.

CARDIUM. A genus of Mollusca belonging to the *Cardiaca*. The foot is largely developed, and is a most important organ to the animals, it being used by most of them not merely for progression, but in the excavation of hollows in the sand or mud of the shores on which they dwell. As usually seen, the foot of the *Cardium*, or Cockle, when extended, tapers gradually to a point; and as its diameter is at its largest point much less than the breadth of the shell, it is not apparent by what means

CARDIUM FILIXIA.

the hole that is excavated is made sufficiently large for the reception of the latter: this, however, is accomplished by the distension of the foot with water, through a tube which opens just within the mouth; and thus the size of the borer becomes so nearly equal to that of the shell, that it is enabled, by rotatory motions often repeated, to excavate a burrow large enough to receive the animal with its shell. The shell is generally white, with sometimes a bluish or yellowish cast; it has twenty-six longitudinal ridges, is transversely wrinkled, and has somewhat imbricated striae. The Cockles, with few exceptions, inhabit the ocean only: they abound most on sandy shores; and are used as a wholesome and nourishing food. The most common species is the Edible Cockle (*Cardium edule*).

Cardium Bechei. This beautiful species (which is a native of the Eastern seas) is dedicated to Sir Henry de la Beche, by its discoverer, Sir E. Belcher, and is described in the "Proceedings of the Zoological Society" (March, 1847), as without exception the most striking and distinct from any hitherto known that can well be imagined. In colour it is of a pure rose tint, with the following singular contrast of character. The middle and anterior portion of the shell is smooth, presenting a peculiar soft velvety appearance, the effect of its being minutely decussated with concentric and radiating

striae, and covered with an exquisite thin shining horny epidermis, disposed in fine concentric cords, abruptly terminating at the posterior area. The posterior portion, accordingly destitute of epidermis, is very thickly rayed with ribs of short compressed spines, as if the delicately clad surface of the shell had been thus far ploughed up, as it were, into furrows.

CARDINAL-BIRD. [See GEOSBEAK.]

CARDUELIS. A genus of Passerine birds, of the Finch tribe. [See FRINGILLIDÆ: GOLDFINCH.]

CARIAMA. A Gallatorial bird, of the genus *Dicholophus*, the species being *D. cristatus*.—of the size of a heron, inhabiting the great mountain plains of Brazil, "where its sonorous voice often breaks the silence of the desert." Its retired habits are well described by Mr. Broderip: "A tenant of the vast solitudes that form its wide-spreading home, it flies from the face of man; and being almost always on the watch, is very difficult of approach. Stalking slowly on the plain, its eye instantly notes the distant intruder, and, after a moment's hesitation, it decides either to stay or fly, according to the circumstances. Those who have had the best opportunities of observing them in their native wilds, state that the hunters, though surrounded by these birds, cannot, without considerable labour, obtain them. As soon as the bird perceives that it is pursued, it sets off with great rapidity; the pursuer follows on horseback, but it is not till after a sharp and tedious course, with all its turnings and windings, that the Cariama, wearied out, either crouches on the ground, or alights on some bush or tree. Till this happens, the horseman in vain seeks for an opportunity to throw his lasso or pull his trigger. But," adds the writer, "wild as the bird is in its natural state, it is easily domesticated, and will live sociably with the other tenants of the poultry-yard." The Cariama is about two feet eight inches in length: it has an ornamental tuft on the head; the neck covered with long, loose feathers, like those of the bittern; legs long; feet long and slender; and tail rounded. The plumage on the upper part of the bird is brown, and the under parts whitish; the neck feathers are finely rayed with zig-zags of darker brown than the general colour; the wings are dark, traversed with white bands and dotted: the tail feathers are blackish, with white extremities; and the plumage on the front of the neck is prettily variegated with white and brown. The bill is of a bright coral red; and the legs and feet are of an orange red. It feeds chiefly upon lizards and insects. The anatomical structure of the Cariama is interesting to zoologists, on account of the relation it bears both to the waders and gallinaceous birds.

CARINARIA. A genus of Gasteropodous Mollusca, with an elongated, subcylindrical, transparent body, furnished with a sort of fin which performs the part of a rudder. The shells of this genus were formerly known

to collectors under the name of "Venus's Slipper," and "Glass Nautilus." A species is found in the Mediterranean, where it is said to feed on small jelly-fish (*Medusa*), and even true fish, as, for instance, the dwarf Atherine (*Atherina nana*.)

CARNARIA. An immense assemblage of unguiculated quadrupeds, belonging to the third order of Mammalia, and which possess, in common with Man and the Quadrumana, the three sorts of teeth, but have no opposable thumb to the fore-feet.

CARNIVORA. The term applied to the fifth order of Quadrupeds, or Beasts of Prey, which in the structure of their teeth and digestive apparatus, and in their general conformation, show that they are peculiarly adapted for destroying living animals, and for tearing and devouring flesh. In the greater number of the members of this order, the size of the canine teeth is the most obvious mark of distinction; these are large, strong, and pointed, and project somewhat forwards, so as to present themselves rather in front of the line of the other teeth. Between the canines of the two sides are six incisor teeth in each jaw, which are provided

SKULL OF THE LION

with sharp cutting edges. The molar teeth, situated behind the canines, are of three kinds;—those which immediately follow the canines, being more or less pointed, and termed *false molars*; the next being especially adapted for dividing and lacerating animal muscle, by the sharp edge of its summit, and termed *carnivorous teeth*; and the last, or hindmost, being more or less rounded or *tuberculated*. The proportion which these different classes of molar teeth bear to each other in degree and development, accords with the relative carnivorous propensity of the different families; for instance, it may be laid down as a general rule, that those carnivorous animals which have the shortest jaw and the least development of the false molars are those in which the sanguinary propensity and the destructive power co-exist in the highest degree. It should also be remembered that the articulation of the jaw does not permit of horizontal movement, the power being simply that of opening and shutting, like a pair of shears. In these, as indeed in all animals, the structure is admirably adapted to their habits. They feed on living animals and are therefore swift to pursue, and strong to overpower them; they are armed with formidable teeth and claws to tear them in pieces; their sight is keen, and even more so by night than by day; their sense of smell is acute, and their power of hearing delicate;

their feet are soft, to enable them to steal silently on their prey; their bodies are long and flexible, so that they may glide unseen; and, finally, their supply of food being uncertain, they are capable of long abstinence.

In every order there is one principal group, which possesses the characteristics of the order in the highest perfection; though the necessary imperfection of all artificial systems of arrangement causes animals to be grouped together, which, although agreeing in very many points, yet differ essentially in others. Thus Lions and Tigers are the principal or tropical group of Carnivora, yet in the order are included Bears, Racoons, &c., which feed principally on vegetables. The Carnivora are divided into—1. The *Plantigrades*, or those which walk on the entire soles of their feet; 2. *Digitigrades*, or those which walk on their toes; 3. *Amphibia*, or *Amphibious Carnivora*. The *Plantigrades* comprise Bears, Badgers, Racoons, Gluttons, and *Coitondis*. The structure of their feet causes these animals to be slow; but as their food is principally vegetable, speed is not required. The same structure gives them great facility in raising themselves on their hind feet. The *Digitigrades* comprise Lions, Tigers, Cats, Dogs, &c. This structure gives swiftness. This division is also characterized by the claws being retractile: thus preserving them from injury, and keeping them sharp for use when required. The *Amphibia*, or *Amphibious Carnivora*, comprise the Seals and Sea-horses, distinguished by having very short hind legs, and the fore legs formed for swimming.

As we shall have occasion to recur to this subject in describing various animals whose propensities are decidedly carnivorous, though differing in the degree, we shall for the present merely add, that the muscular energy of the Carnivora is very great; their respiration and circulation very active; and the demand for food, as a natural consequence, very constant.

CARP. (*Cyprinus carpio*.) The genus of Malacopterygious abdominal fish, of which this species is the best known, may be easily distinguishable by the small mouth, toothless jaws, and gills of three flat rays. The tongue and palate are smooth, but the gullet is admirably constructed for mastication, having large teeth attached to the inferior pharyngeal bones, which press the food between themselves and a gelatinous knob, connected with a bony plate that is united with the first vertebra, commonly called the carp's tongue. They have but one dorsal fin, and the body is covered with scales, generally of a large size. They frequent fresh and quiet waters, feeding on herbs, grain, and even mud, being, perhaps, the least carnivorous of the finny race. The most noted are the **COMMON CARP**, and the **GOLDEN CARP** or **GOLD-FISH** (*Cyprinus auratus*).

The **COMMON CARP** (*Cyprinus carpio*) is found in most of the lakes and smaller rivers of Europe; but those of the southern and temperate parts are most congenial to it, and it is said to decrease in size the further it is removed to a northern region. It is generally

supposed that Carp were introduced into this country about the year 1500; but this is a fact of very little real importance, since they have long become denizens of most of our fish ponds and many of our rivers. They frequent the deepest places, and thrive best in such as have clayey or marly sides, and

CARP. — (*CYPRINUS CARPIO*.)

are well provided with aquatic vegetables; their usual food consists of worms and other insects: but grain of various sorts, and garbage, are frequently thrown into the pond, with a view to aid in fattening them. The Carp is an extremely prolific fish, and the quantity of roe is so great that it is said to have sometimes exceeded the weight of the emptied fish itself when weighed against it.

The age to which the Carp arrives is very great, and several well authenticated instances are adduced of their arriving at that of considerably more than a century: some writers, indeed, affirm that they have been known to live to the age of two hundred years! The usual length of Carp in this country is from about twelve to sixteen inches; but in warmer climates they are frequently more than three feet long, and weigh twenty or thirty pounds. The general colour is a yellowish olive, much deeper or browner on the back, and the sides slightly tinged with a golden hue: the scales large, round, and very distinct; the head large, and the mouth furnished with a moderately long cirrus or beard: above which is a shorter one. The fins are violet brown, except the anal, which has a reddish tinge: the dorsal fin is broad or continued to some distance from the middle of the back towards the tail, which is slightly forked, with rounded lobes.

CARPENTER BEE. (*Xylocopa*). The name given to a very large genus of Hymenopterous insects; not one species of which has yet been found in the British Islands. They are generally of a very dark violet blue, and of considerable size. As an exemplification of this peculiar exotic genus, we may mention the Violet Carpenter Bee (*X. violacea*), a very common insect about Paris. Their bodies are of a very deep blue colour, smooth, and shining; their fore-wings are of a deep violet colour: on their sides, the hinder part of their bodies, and their breasts, there are long black hairs. As we have mentioned, they are not indigenous in this country; but in France and the southern parts of Europe there is scarcely a garden where some of them may not be found at different seasons of the year. They generally form their nests in pieces of half-rotten wood; and the holes are not made directly

forward, but inclining to one side, and having apertures large enough to admit a finger; from which run their inner apartments, each generally twelve or fifteen inches long, and diverging into others. In each of these cavities they deposit ten or twelve eggs, which are covered with a sort of paste, serving for the protection of the young insects, as well as for their nourishment. The females perform all the labour; and the males have no stings. In the British Museum cases, may be seen specimens of wood bored by a North American species, or, we should rather say, with holes made by their powerful jaws. [See APIDÆ: BEE.]

CARPET (MOTHS). A name applied by insect collectors to various species of Moths, of the genera *Harpalycæ*, *Cidaria*, *Larentia*, *Chæoria*, and *Alicis*.

CARPINCHO. The Capybara, or Waterhog. From the dung of this, the *Myrapetra scutellaris*, a species of wasp found near Buenos Ayres, constructs its pasteboard nest. [See CAPYBARA.]

CARRIER PIGEON. [See PIGEON.]

CARYOPHYLLÆA. A genus of Zoophytes, belonging to the *Madrephyllia*, or the first section of the stony *Zoantheria* of De Blainville. The cells in this genus of Zoophytes are furnished with radiating

CARYOPHYLLÆA.

plates, striated externally, and collected into a solid conical polyparium fixed at the base. In the British Museum are many very fine specimens of this genus, which is found both in a recent and fossil state.

CASHMIRE GOAT. [See GOAT.]

CASSIS. A genus of Molluscous animals inhabiting an oblong shell: found in the seas of warmer climates. [See HELMET SHELL.] The well-known large species of this genus are used as ornaments on chimney pieces, grottos, &c., and are remarkable for the triangular disc, presented by the inner lip, which is thickened and spread over the body whorl, and the angulated outer lip; and as this thickening of the lip takes place at various stages of growth, the same triangular plane is observable at different parts of the spire.

CASSIDA. A genus of Coleopterous insects, of the family *Cassididæ*, or Tortoise-Beetles. They have a flattened body, surrounded by a margin, which is formed by a

CASSIDA VIRIDIS.

prolongation from the thorax and elytra, and which even conceals the head; and they are able to lie so close upon the surface of the leaves, that no part of the body or limbs can be seen. Their colours are much varied, and often very prettily arranged in spots, points, rays, &c. The family is very numerous in genera and species, and among the exotic species are several of great beauty; but when dead, or taken out of spirits of wine in which they may have been preserved, their metallic brilliancy for the most part disappears.

The COMMON GREEN CASSINA, or *Cassida viridis*, is often seen during the summer months in gardens on the leaves of mint, &c. Its length is not quite a quarter of an inch; its shape oval, and its colour bright green above, the body or under part being perfectly black. The larva, which is of a highly singular appearance, is oval, of a yellowish brown colour, and has the body edged with a row or fringe of projecting fibres, the two terminal ones being much longer than the rest, and generally carried in an upright position while the insect is in motion. When ready to assume the chrysalid form, it fastens itself to a leaf, and, casting its skin, commences its new state of existence; and from the chrysalis, in the space of three weeks, comes forth the perfect insect.

CASSOWARY. (*Casuarus*.) This large and powerful Struthionidous bird is a native of Java and the adjacent islands of the Indian Archipelago, and is called the *galeated* or *helmeted* Cassowary, from its head being surmounted by a sort of osseous crest or horny helmet. The skin of the head and upper part of the neck are naked, of a deep-blue and fiery-red tint, with pendent caruncles, similar to those

CASSOWARY — (CASUARIUS GALEATUS.)

of the Turkey-cock. It is much inferior in size to the Ostrich, its height when erect being little more than five feet; but it is robustly built, and very strong. From the

form of its head, and bright eyes, it would be reasonable to infer that the Cassowary was of a fierce and threatening nature; this, however, is not a true indication of its character, which is rather timorous and shy. The shortness of the wings totally unfits it for flying, and its pectoral or wing-muscles are comparatively slight and weak. All the feathers of the Cassowary are of the same kind, being entirely designed for covering, and externally are all of one colour. They generally grow double, having two long shafts growing out of a short one attached to the skin; yet its whole plumage is so poorly supplied with feathers as to resemble, at a little distance, a coat of coarse or hanging hair. The feathers on the head and neck are so short and scattered, that the skin appears naked, except towards the hind part of the head, where they are somewhat longer.

In many important points of internal structure the Cassowary differs from the Ostrich; particularly in the conformation of its digestive organs. The intestines are short, and the *cæcum* small; there is no stomach intermediate to the crop and gizzard, and the *cloaca* is not larger, in proportion, than that of other birds. It feeds on fruits, eggs of birds, and tender herbage, but not on grain. It eats its food with great voracity, and, like the ostrich, swallows bits of iron, brick, glass, &c., which have the same effect in assisting the digestion of these large birds, that gravel has with ordinary fowls. The Cassowary is an amazingly swift runner; and its mode of progression, being unaltered by wings, is as peculiar as it is efficient. It appears to strike out powerfully with one leg, so as to project its body violently forward with a bounding motion, far surpassing the speed of a horse. It also kicks violently when, in a state of captivity, it is provoked to anger, and can inflict a very severe blow. The eggs of the galeated Cassowary are of a greyish-ash colour, verging to green, and are neither as round nor as large as those of the Ostrich: the shell is not very thick, and is marked by numerous little green tubercles.

CASTOR. [See BEAVER.]

CASUARIUS. [See CASSOWARY.]

CAT. (*Felis*.) All animals of the Cat kind, though they may differ greatly in size and colour, are in their wild state equally characterized by fierceness, artfulness, and rapacity. It is not, however, in this place that the habits, propensities, or anatomical structure of the feline race generally are to be discussed: the reader must refer to the article *FELIS* for such remarks on those heads as we have deemed it essential to introduce.

The Cat, (*Felis catus ferus*), in a state of natural wildness differs in some slight particulars from the domestic animal, having a somewhat shorter tail in proportion, a flatter and larger head, and stronger limbs. The colour of the wild Cat is commonly a pale yellowish-grey, with dusky stripes; those on the back running lengthwise, those on the sides transversely and with a curved di-

rection: the tail is annulated with several alternate circles of blackish-brown and dull white; and the tip of the nose and the lips are black: they are, however, not uniformly alike in every particular. The manners of the wild Cat resemble those of the lynx, and several others of this genus; living in woods, and preying on young hares, birds, and a variety of other animals, which it seizes by surprise. "The wild Cat," says Mr. Pennant, "may be called the British tiger; it is the fiercest and most destructive beast we have; making dreadful havoc amongst our poultry, lambs, and kids. It inhabits the most mountainous and woody parts of these islands, living mostly in trees, and feeding only by night. It multiplies as fast as our common Cats; and often the females of the latter will quit their domestic mates, and return home pregnant by the former."

The varieties of this animal in a domestic state are very numerous: it is either entirely black; black and white; black, fulvous, and white (called the Tortoise-shell or Spanish Cat); entirely white; fulvous and white; dun colour or tawny, either plain or striped; tabby, boldly striped; slate-coloured or blue-grey (called the Chartreux Cat); slate-coloured with very long fur, especially on the neck and tail (the Persian Cat); long hair of silvery whiteness and silky texture (called the Angora Cat); and, lastly, with pencilled or tufted ears, like a lynx, which sometimes though rarely, takes place. Of all the above varieties, the Persian and the Angora are the most remarkable.

Although the Cat is capable of showing considerable fondness for an individual, it seems to be a pretty general opinion that she seldom, if ever, confides fully, even in the warmest demonstrations of kindness; but, being highly sensitive and fond of ease, evinces little anxiety, except for the continuance of her enjoyment. Yet, with all the prejudice that exists against the furtiveness and treachery of the species, no one can deny that, when well educated, the Cat possesses qualities which well entitle her to the regard and protection of mankind; and if she does not exhibit the vivid and animated attachment of the dog, she is still of an affectionate and gentle disposition, and grateful to her benefactors. Nor does any animal, whose habits we have the opportunity of accurately observing, exhibit a greater degree of maternal tenderness; the extreme assiduity with which she attends her young, and the fondness which she shows for them, never fail to attract attention.

At what period Cats became inmates of human habitations, it is scarcely possible, at this period, to determine. Beyond doubt, their usefulness in destroying rats, mice, &c. first introduced them to notice; and there is good reason to believe that they were originally domesticated in Egypt. That Cats, closely allied to the domestic variety, were trained to catch birds, is well known to every one who has seen an Egyptian painting (or a copy from it) in the British Museum, where a cat with a black stripe on the heels (supposed to be the *Felis caligata*) is so represented. The Cat belongs to a genus better armed for

the destruction of animal life than all other quadrupeds. The short and powerful jaws, moved by vigorous muscles, are supplied with most formidable trenchant teeth: a cunning disposition, combined with nocturnal habits and much patience in pursuit, gives them great advantages over their prey; and their keen, lacerating claws enable them to inflict a certain death-blow. All animals considerably weaker than themselves prove objects of pursuit: but the mouse is their favourite game; for which they will patiently wait for a whole day till the victim comes within reach, when they seize it with a bound, and after playing with it put it to death.

The pupil of the eye in most animals is capable of but a small degree of contraction and dilatation; it enlarges a little in the dark, and contracts when the light pours upon it too profusely; but in the eyes of Cats, this contraction and dilatation is so considerable, that the pupil, which by day appears narrow and small, by night expands over the whole surface of the eye-ball, and gives the eyes a luminous appearance. By means of this peculiar structure, their eyes are better adapted for vision at night than in the day-time; and they are thus fitted for discovering and surprising their prey.

Cats are extremely fond of strong-smelling plants, and will roll in valerian till they seem almost mad with excitement. Personally, it is a very cleanly animal, avoiding to step in any sort of filth, concealing its excrement in the earth with great care, and preserving its fur in a very neat condition; which being generally clean and dry, readily yields electric sparks when rubbed. The Cat goes with young for sixty-three days, and brings forth from three to six at a litter, which remain blind for nine days.

CATASTOMUS. A sub-genus of Malacopterygious fishes, of the *Cyprinidae* family, inhabiting the fresh waters of North America. There are many species, the generic description of which is as follows:—Back with a single fin: gill-membrane three-rayed: head and opercula smooth: jaws toothless and retractile: mouth beneath the snout; lips plaited, lobed, or carunculated, suitable for sucking: throat with pectinated teeth. In almost all the species, the scales are marked with radiated lines, and finned on their edges; their form more or less rhomboidal or roundish. In the intestines, river-shells (*Lymnaea*, *Bulinus*, &c.), which dwell on aquatic plants and on rocks or bottoms of rivers, are found; the *Catastomi* being enabled to take these shells by means of their lips, which are protruded forwards by their jaws. One species will be sufficient for us to describe.

CATASTOMUS HUDSONIUS; or GREY SUCKING CARP. This is a common fish in all parts of the fur countries, abounding in the rivers, and even in land-locked marshes and ponds, but preferring shallow grassy lakes with muddy bottoms. In the beginning of summer it may be seen in numbers forcing its way up rocky streams, and even heaving strong rapids, to arrive at its proper spawning places in stony rivu-

lets; but it soon afterwards returns to the lakes. Its food appears to consist of soft insects and minute crustacea. In the spawning season (June) it may be readily speared, or even taken by the hand, in shallow streams; but in the winter and autumn it is caught in nets. It is a very soft watery fish, but devoid of any unpleasant flavour, and is excellent for making soup. Like its congeners, it is singularly tenacious of life, and may be frozen and thawed again without being killed. It is about twenty-one inches long; the head is smooth, flattened laterally, with an obtuse snout; the depth of the body exceeds its thickness rather more than one-half. The lateral line runs equidistant from the back and belly, straight till it comes opposite to the anal fin, when it inclines upwards at a very obtuse angle, and passes along the middle of the tail, giving that member a direction slightly different from that of the body. Scales for the most part broadly oval, or nearly orbicular, and of a medium size. Mouth retractile, placed under the snout; lips studded with large soft papillae; but there are no barbels. The pectoral fins are elliptical; the ventrals obovate; the dorsal fin is nearly quadrangular; the anal extends to within its own length of the caudal, and when it is turned backwards its tip reaches the base of the caudal, which is slightly crescentic. The back and sides of this fish are bluish-grey with considerable lustre, the back being darkest, and the tint of the sides gradually passing into the pearl-white of the belly. Dorsal and caudal fins bluish-grey; pectorals and ventrals ochre-yellow, tinged with red; anal flesh-red. Among the other best-known species are the Red Sucking Carp (*Catostomus forsterianus*); the Gilt Sucking Carp (*Catostomus aureolus*); and the Black Sucking Carp, or Shoemaker (*Catostomus nigricans*).—These, as well as the preceding, are all described by Sir John Richardson, the most distinguished Ichthyologist of this country, in his Fauna Boreali Americana, and the Supplements to different Arctic Voyages.

CAT-BIRD. (*Turdus Mimus* *felivox*.) The celebrated American ornithologist, Wilson, has given an account of this bird in a style so amusing, that we are tempted to lay it almost entire before our readers. "In spring or summer," says he, "on approaching thickets or brambles, the first salutation you receive is from the Cat-bird; and a stranger, unacquainted with its note, would instantly conclude that some vagrant orphan kitten had got bewildered among the briars, and wanted assistance; so exactly does the call of the bird resemble the voice of that animal. Unsuspicious, and extremely familiar, he seems less apprehensive of man than almost any other of our summer visitants; for whether in the woods, or in the garden, where he frequently builds his nest, he seldom allows you to pass without approaching to pay his respects in his usual way. This humble familiarity and deference, from a stranger, too, who comes to rear his young, and spend his summer with us, ought to entitle him to a full share of our hospitality.

Sorry I am, however, to say, that this, in too many instances, is cruelly the reverse."

The Cat-bird generally succeeds in building his nest about the beginning of May. The place chosen for this purpose is usually a thicket of briars or brambles, a thorn bush, thick vine, or the fork of a small sapling; no great solicitude is shown for concealment, though few birds appear more interested for the safety of their nest and young. The materials are dry leaves and weeds, small twigs, and fine dry grass; the inside is lined with the fine black fibrous roots of some plant. The female lays four, sometimes five, eggs, of a uniform greenish blue colour, without any spots. They generally raise two, and sometimes three, broods in a season.

"In passing through the woods in summer, I have sometimes amused myself with imitating the violent chirping or squeaking of young birds, in order to observe what different species were around me,—for such sounds, at such a season, in the woods, are no less alarming to the feathered tenants of the bushes, than the cry of fire or murder in the streets is to the inhabitants of a large and populous city. On such occasions of alarm and consternation, the Cat-bird is the first to make his appearance, not singly, but sometimes half a dozen at a time, flying from different quarters to the spot. At this time, those who are disposed to play with his feelings may almost throw him into fits, his emotion and agitation are so great, at the distressful cries of what he supposes to be his suffering young. Other birds are variously affected, but none show symptoms of extreme suffering. He hurries backwards and forwards, with hanging wings and open mouth, calling out louder and faster, and actually screaming with distress, till he appears hoarse with his exertions. He attempts no offensive means; but he bewails—he implores—in the most pathetic terms with which nature has supplied him, and with an agony of feeling which is truly affecting. Every feathered neighbour within hearing hastens to the place, to learn the cause of the alarm, peeping about with looks of consternation and sympathy. But their own powerful parental duties and domestic concerns soon oblige each to withdraw. At any other season the most perfect imitations have no effect whatever on him.

"The Cat-bird is one of our earliest morning songsters, beginning generally before break of day, and hovering from bush to bush, with great sprightliness, when there is scarce light sufficient to distinguish him. His notes are more remarkable for singularity than for melody. They consist of short imitations of other birds, and other sounds; but, his pipe being rather deficient in clearness and strength of tone, his imitations fail where these are requisite. Yet he is not easily discouraged, but seems to study certain passages with great perseverance; uttering them at first low, and, as he succeeds, higher and more free, nowise embarrassed by the presence of a spectator even within a few yards of him. On attentively listening for some time to him, one can

perceive considerable variety in his performance, in which he seems to introduce all the odd sounds and quaint passages he has been

CAT BIRD.—(TURDUS [MIMUS] FELIX)

able to collect. Upon the whole, though we cannot arrange him with the grand leaders of our vernal choristers, he well merits a place among the most agreeable general performers. In summer, scarcely a thicket in the country is without its Cat-birds; and, were they to fly in flocks, like many other birds, they would darken the air with their numbers. In their migrations they keep pace with the progress of agriculture; and the first settlers in many parts of the Genesee country have told me, that it was several years after they removed there, before the Cat-bird made its appearance among them. With all these amiable qualities to recommend him, few people in the country respect the Cat-bird; on the contrary, it is generally the object of dislike; and the boys of the United States entertain the same prejudice and contempt for this bird, its nest and young, as those of Britain do for the Yellow-hammer, and its nest, eggs, and young. I am at a loss to account for this cruel prejudice. Even those by whom it is entertained can scarcely tell you why; only they 'hate Cat-birds;' as some persons tell you they hate Frenchmen, they hate Dutchmen, &c.; expressions that bespeak their own narrowness of understanding and want of liberality. Yet, after ruminating over in my own mind all the probable causes, I think I have at last hit on some of them; the principal of which seems to me to be a certain similarity of taste, and clashing of interest, between the Cat-bird and the farmer. The Cat-bird is fond of large ripe garden strawberries; so is the farmer, for the good price they bring at market: the Cat-bird loves the best and richest early cherries; so does the farmer, for they are sometimes the most profitable of his early fruit, &c. Perhaps, too, the common note of the Cat-bird, so like the mewing of the animal whose name it bears, and who itself sustains no small share of prejudice, the homeliness of his plumage, and even his familiarity, so proverbially known to beget contempt, may also contribute to this mean, illiberal, and persecuting prejudice; but, with the generous and the good, the lovers of nature and of rural charms, the confidence which this familiar bird places in man by building in his garden, under his eye, the music of his song, and the interesting playfulness of his manners, will always be more than a recom-

pence for all the little stolen morsels he snatches.

"The Cat-bird measures nine inches in length; at a small distance he appears nearly black; but, on a closer examination, is of deep slate colour above, lightest on the edges of the primaries, and of a considerably lighter slate colour below, except the under tail-coverts, which are very dark red; the tail, which is rounded, and upper part of the head, as well as the legs and bill, are black. The female differs little in colour from the male." The habits, manners, and general appearance of the Cat-bird differ so little from the Thrushes, that the naturalist to whom we are indebted for the foregoing particulars does not hesitate to place him in the genus *Turdus*. He is a great and determined enemy to the common black snake, or horse-runner (*Coluber constrictor*), which rifles its nest whenever an opportunity offers. As the Cat-bird uniformly attacks or pursues this snake, and is frequently seen in the act of hopping eagerly after it, numerous ridiculous stories are related of its being fascinated by the snake; it is, however, well known to naturalists that the bird is almost uniformly the aggressor and victor, driving the reptile to its hiding-place.

CATERPILLAR. The name given to the larva of lepidopterous insects; of which we have spoken at some length in the article **BUTTERFLY**, and to which the following, from "Brande's Dictionary of Science" (art. *Lepidoptera*), may be added. "They have six squamous or hooked feet, which correspond to the legs of the perfect insect, and from four to ten additional membranous ones, or *propodes*; the two last of which are situated at the posterior extremity of the body. Those Caterpillars which have but ten or twelve in all, have been called, from their mode of progression, *Geometrae*. Several of these geometers, when at rest, remain fixed to the branches of plants by the hind feet alone, whence in the form, colour, and directions of their body, they resemble a twig. The body of these larva is generally elongated, almost cylindrical, soft, variously coloured; sometimes naked, and sometimes covered with hairs, tubercles, and spines. It is composed of twelve segments or annuli, exclusive of the head, with nine stigmata on each side. Their head is invested with a corneous or squamous dermis, and presents on each side six shining granules, which appear to be ocelli; and it is furnished with two very short and conical antennae, and a mouth composed of strong mandibles; two maxillae, a labrum, and four small palpi. Most Caterpillars feed on the leaves of plants; some gnaw their flowers, roots, buds, and seeds; others attack the ligneous or hardest parts of trees, softening it by means of a fluid which they disgorge. Certain species attack our woollens and furs, thereby doing us much injury; even our leather, bacon, wax, and lard are not spared by them. Several confine themselves exclusively to a single article of diet; others are less delicate, and devour all sorts of organized matters. Some of them form societies, and frequently live

under a silken tent, spun by them in common, which even shelters them in winter. Several construct sheaths for themselves, either fixed or portable; others make their abode in the parenchyma of leaves, where they form galleries. The greater number are diurnal; the others never issue forth but at night."

There are perhaps no insects which are so commonly and so universally destructive as Caterpillars; they are inferior only to locusts in voracity, and equal or exceed them in their powers of increase, and in general are far more widely spread over vegetation. As each female Butterfly or Moth usually lays from two hundred to five hundred eggs, one thousand different kinds of butterflies and moths will produce, on an average, three hundred thousand caterpillars; if one half of this number, when arrived at maturity, are females, they will give forty-five millions of caterpillars in the second, and six thousand seven hundred and fifty millions in the third generation! These data suffice to show that the actual number of these insects, existing at any one time, must be far beyond the limits of calculation.

CATHARTES. [See TURKEY BUZZARD.]

CATTLE. A collective term, denoting all animals of the bovine or ox kind. The domestic cattle of Britain may be divided into two races: those of large size, adapted for the plains; and those of smaller size, adapted for the mountains. Of each of these classes there are several breeds; such as the Highland and the Welch cattle, among the latter; and the Lancashire, the Yorkshire, and the Herefordshire cattle, among the former. There is also an intermediate breed, adapted for moderately hilly countries; such as the Galloway and Fife breeds in Scotland, and the Alderney and Guernsey cattle in England. The best beef brought to the London market is that of cattle of the Highland breed fed in English pastures, or on turnips. The best milk cow for general purposes is the Ayrshire; the best for cream and butter, the Alderney; and the best for immense quantities of milk, the Lancashire. Hence the latter are generally employed in public dairies, the Ayrshire by farmers and cottagers, and the Alderney by the higher classes.

CATURIDÆ. [See SUPPLEMENT.]

CAVY. (*Cavia*.) A genus of Rodents inhabiting tropical America. They are distinguished by the possession of eight grinders on either side of the jaw, and by two wedge-shaped incisive in front. The fore-feet are either three or four-toed, the hind-feet being generally tridactylous and in some cases five-toed, with the two outer digits feebly developed; tall short or absent; and no clavicle. They have generally a slow, and sometimes a leaping pace; they live on vegetable substances, and in their natural state inhabit excavations under ground, or beneath the roots of trees, or other recesses which they either find ready prepared, or form for themselves.

The **COMMON CAVY**, or **GUINEA-PIG**. (*Cavia Cobaya*.) From the beauty and variety of its colours, and the neatness of its appearance, this species must have early attracted the attention of those Europeans who first visited South America; but it has

COMMON CAVY, OR GUINEA-PIG.
(*CAVIA COBAYA*.)

been so long domesticated in this and other countries, as now to have become quite naturalized in the Old World. Its ears are large, broad, and rounded at the sides; its upper lip is half divided; and its hair is erect, somewhat resembling that of a young pig. Its colour is white, varied with orange and black in irregular blotches. It has four toes on the fore-legs, and three on the hind; and is destitute of a tail. In its wild state it lives in societies, inhabiting dry lands covered with low brushwood; and remains concealed during the day, coming forth on the approach of evening to seek its food. It possesses neither cunning to avoid danger, strength to resist, nor swiftness to escape from it; and nothing could save the race from extermination, were it not for its extraordinary rapidity of multiplication. The usual litter consists of six, eight, or ten; and so prolific is it that it breeds almost every two months. The young very soon acquire the necessary degree of strength and perfection of their species, though they continue to grow till seven or eight months. They are very tender animals, and susceptible of cold; and should therefore be provided with warm receptacles to retire into in bad weather. In their habits they are extremely neat, and may be frequently observed in the act of smoothing and dressing their fur. Their general voice is a sort of a grunting squeak, and sometimes a shriller or sharper cry.

The **SPOTTED CAVY** (*Calogenys paca*) is a large species, measuring nearly two feet in length. It is found in Guiana, Brazil, and other parts of South America; inhabiting holes formed underground, and principally near the banks of rivers. Its shape is thick and clumsy, somewhat like that of a pig, for which reason it has been sometimes called the hog-rabbit. It has five toes on each foot, and only the mere rudiment of a tail. The upper jaw is longer than the lower; the ears are short and naked; the lip is divided like that of a hare; and it has long whiskers. The body is covered with coarse, short, thinly-scattered hair of a dusky colour; the throat, breast, and belly are of a dingy white; and on each side the body run five rows of roundish, slightly angular spots. The Spotted Cavy is a nocturnal animal, residing in a solitary manner in his hole nearly the whole day. In a domestic state

it readily feeds on almost any kind of vegetable diet, and is particularly fond of sugar and fruits. By the South Americans it is much esteemed as an article of food. [See AGOUTI; CAIYBAKA; PACA, &c.]

CEBIDÆ. A term used to include all the Monkeys of the American continent; which differ in several respects from those of the Old World; viz. by a partial or complete absence of the thumb upon the hands; the callosities and cheek-pouches are altogether absent; there is a very considerable space between the nostrils; the tail is usually of great length, never absent, and often prehensile. They are very numerous in those vast forests which occupy the plains between the rivers Orinoko and Amazon. [See MONKEY.]

CEBRIO: CEBRIONIDÆ. A genus and family of Coleopterous insects, of small extent, but comprising several striking peculiarities of structure. The body is of an oblong oval form, of a firm consistence like the Elateridæ, arched above and deflexed in front; the mandibles strong, curved, and entire at the tip; the thorax broadest behind, with the posterior angles acute; and the antennæ generally longer than the head and thorax, and serrated or pectinated in the males. These insects are of moderate size; and their colours generally dull and obscure: for the most part they are inhabitants of the south of Europe, and the north of Africa; and but little is known of their habits.

Some of the genera are most remarkable for their beautiful pectinated antennæ, which in the male sex have the branches often of

RHIPICERA MARGINATA

very great length. By some authors these are regarded as a separate family, under the name of *Rhipiceridæ*. We figure a beautiful Brazilian species, which is of a blackish green, and pubescent: the anterior and lateral margins of the elytra are yellow: hence it is called *Rhipicera marginata*. The figure in outline represents the beautiful pectinated antenna of the male, considerably magnified.

CECIDOMYIA: CECIDOMYIDÆ. A genus and family of two-winged flies, of which there are many species. They are always of small size; many of them deposit their eggs upon the tender buds of various kinds of plants; others upon the young sprigs, and some upon the flowers. One species (*Cecidomyia salicina*) fixes each of its

eggs on a bud of the willow, which becomes enlarged, and ultimately forms a gall in which the larva is lodged and nourished. Another (*Cecidomyia tritici*), known as the Wheat-fly, may sometimes be seen, in great abundance, flying about wheat fields in the month of June. This little fly deposits its eggs in the centre of the corolla, where the larvæ are hatched; and it is probably by devouring the pollen that they are most injurious to the plant. Another species (*Cecidomyia destructor*), known in America under the name of the Hessian-fly, attacks the lower part of the stem of the wheat. Dr. Asa Fitch, an American naturalist, has just published a most admirable and readable account of the *Cecidomyia*, from which we shall make extracts in our article "Wheat-fly." [See WHEAT-FLY and HESSIAN-FLY.]

CECILIANS. A name given to a genus of naked serpents, from their supposed blindness.

CENTIPEDE. (Scolopendra.) A genus of carnivorous annulosa belonging to the order *Myriapoda* of Cuvier. They are distinguished by having antennæ of fourteen joints or upwards; a mouth composed of two mandibles; a quadrid lip; two palpi, or small feet, united at their base; and a second lip, formed by a second pair of dilated feet, joined at their origin, and terminated by a strong hook, having an opening beneath its point, through which a poisonous fluid is thrown out. The body is long, depressed, and membranous, each ring being covered by a coriaceous or cartilaginous plate, and mostly having one pair of feet: the last is usually thrown backwards, and elongated in form of a tail. These insects conceal themselves under the decayed bark of trees, the decayed timbers of buildings, among stones, lumber, and rubbish, whence they sally forth at night in search of prey. In the West India islands, and throughout the hot parts of America, where they multiply rapidly and grow to a large size, they are very formidable pests. The utmost vigilance is necessary, even in cleanly houses, to prevent these creatures from finding their way into the beds; and although they endeavour to escape as soon as a light is brought into the room, and run with considerable swiftness, they are ready to stand on the defensive, and bite severely: they are accordingly very dangerous when once they have entered a bed; the bite being not only exceedingly painful at the moment, but followed by a high degree of local inflammation, and a fever of great irritation. This truly noxious Centipede grows to the size of five or six inches in length, and is a formidable inmate of most of the houses in tropical regions. In different countries the species vary: the one common in England is of a

CENTIPEDE.

reddish-brown colour, about an inch long, with a flat, thin body, and yellowish legs.

Dr. Leach made it the type of his genus *Lithobius*, a word meaning that the Centipede lived under or amongst stones. One species is very common in this country, it is named *L. forficatus*.

There are other species in the collection of the British Museum, from which they were originally described by the late G. Newport, F.R.S., who in 1844 published an admirable monograph of the *Scolopendridæ* and their allies in the 19th volume of the *Linnean Transactions*. From the numerous references to the British Museum, the student will see how rich our great national establishment must be in this important order of the Animal Kingdom.

CENTRISCUS, or **SEA-SNIPE**. (*Centriscus scolopax*.) A genus of Acanthopterygious fishes, principally distinguished by

SEA-SNIPE. — (*CENTRISCUS SCOLOPAX*.)

their having a long tubular snout: the body compressed, and inclining to an oblong oval form; the abdomen carinated; and the belly-fins united. [See *THYMNETRIS*.]

CENTROLOPHUS. A genus of Acanthopterygious fishes, the technical characters of which are:—body elongate, covered with minute scales; teeth small and numerous; palatine without teeth; one long dorsal fin.

CENTRONOTUS. A genus of Acanthopterygious fishes, family *Scomberidæ*; in which the spines are free or unconnected by membrane, and all have ventral fins.

CENTROPOMUS. A genus of Acanthopterygious fishes; a well known species of which is called the Sea-pike (*Centropomus undecimalis*), and is common throughout South America, where it forms a considerable article of consumption. The Sea-pike sometimes weighs as much as twenty-five pounds; the form of its body is elongate; its colour is greenish-brown above, and silvery beneath.

CENTROPRISTES. A genus of Acanthopterygious fishes; one species of which, (*Centropriestes nigricans*), the Black-perch or Black-bass, is of a deep olive-green colour above, and of a pink hue on the under parts; but it is mostly remarkable for having the tail doubly notched, the central and two outer parts projecting.

GENTROPUS. A genus of Scausorial Birds. [See *PICASCANT CUCKOO*.]

CEPHALOPODA. A class of Molluscous animals, characterized by the possession of locomotive organs (or feet) around the head;

they are, however, not feet, but prolonged tentacula, or fleshy processes, which project forwards from the head, and more or less conceal the mouth. In the whole range of molluscous animals, the Cephalopods are the most highly organized; they present undoubted elements of an internal skeleton, and contain digestive, secretory, respiratory, and generative organs. The nervous system of the Cephalopods approaches that of the lower fishes in many particulars; and they are almost exclusively marine in their habits. The natural division of the class is into those Cephalopods which are naked, and those which are testaceous, (i.e. protected by an external shell.) Of the former, the common Cuttle-fish, and of the latter, the Nautilus, may be taken as examples.

CEPHUS. A genus of Hymenopterous insects. The *Cephus pygmaeus*, which is common on flowers, particularly buttercups, is about one-third of an inch long; black, with two yellow fasciæ on the abdomen; and its larva is said to live in the stems of wheat.

CEPOLA. A genus of Acanthopterygious fishes, the bodies of which are much compressed and elongated. [See *BAND-FISH*.]

CERAMBYCIDÆ. A family of Coleopterous insects (*Longicornes*); the most distinguishing feature of which is the very great length of their antennæ. They are found in all parts of the globe, but they abound most in hot climates. They deposit their eggs in old and decaying trees, which the larvæ afterwards feed upon, and thereby assist in removing. The body of the insects is long and subdepressed, occasionally subconvex; the maxillary lobes are distinct and membranaceous; the femora often clavate; and the tarsi short. Mr. Westwood, to whose "Modern Classification of Insects" we are so much indebted, observes that they are "generally of an elegant form, and beautifully variegated in their colours; they are found in forests, hedges, or wood, sitting upon the trunks of trees, or more rarely upon flowers. Some of the exotic species are remarkable for having the antennæ and legs covered with thick pencils of hairs; others are distinguished by the emission of a fragrant odour, not unlike that of attar of roses, which is so powerful, that the insects may be discovered upon trees by passers by, in consequence of the scent diffused through the air, and which is retained for a considerable period after death. Hence the generic names *Callichroma* and *Aromia*, proposed for these insects by Latreille and Serville. The *Cerambyx moschatius*, Linn. (or Musk Beetle, as it is generally but improperly termed, the scent scarcely resembling that of this drug) is the only British species belonging to this scented group: it is more than an inch long, of a fine green colour, and is abundant upon willows in the neighbourhood of London." It has been conjectured that the fragrance, which is always much more powerful in the female, may be intended, like the light of the glowworm, as a guide for the males. The author just

quoted informs us, that the larva of *Cerambyx heros*, which is one of the largest European species, is considered by Latreille to have been the *Cossus* of the ancients, by whom it was esteemed a relishing treat.

CERAMBYX HEROS.

It resides in the oak, occasioning much injury to the timber, by boring large channels in all directions through the trunk of the tree: this is also the case, as regards young willows, with the Musk beetle; the larva of which is of a thick form and fleshy consistence; the head small; the prothorax large and transverse; the meso and meta-thorax very short, the former furnished with a pair of spiracles, and the three thoracic segments having three pairs of very short legs. He further says, "The larvæ of the genus *Callidium* are similar to those of *Aromia* (the Musk beetle) both in form and habits. The places where they reside may be known by the long cylindrical burrows which they form, and which are filled with excrement resembling powdered wood. It is not difficult to keep these larvæ alive in the wood in which they are found, and in which they assume the pupa state; it is very rarely, however, that they can be reared to the imago state. Mr. Kirby has given an interesting account of the proceedings of the larva of *Callidium violaceum*, which, in the larva state, feeds principally upon fir timber, upon which the bark has been suffered to remain after it has been felled; residing under the bark, mining its labyrinth-like passages in every direction, and occasioning much damage by means of its powerful jaws, which resemble a large, thick, and solid section of a cone of horn; the whole of their interior flattened surfaces applied together, so as completely to grind the food. It is described as being destitute of feet, pale, folded, somewhat hairy, convex above, and divided into thirteen segments, with the head large and convex. When full grown, it bores down obliquely into the solid wood to the depth of several inches, where it becomes a pupa."

The collection of these insects in the Bri-

tish Museum is very extensive: their form, colour, and appendages make them always pleasing objects to the sight; while to the Natural Theologian, the part they play in the economy of nature is very apparent and easily demonstrable in many striking ways.

CERASTES. A genus of serpent called in England the Horned Snake, having two small protuberances on its forehead. This animal, which partakes of the nature of viviparous serpents, is remarkable for its almost total abstinence from water. It is found in Lybia, Arabia, &c.

CERBERUS. A sub-genus of Ophiidians. [See SERPENTS.]

CERCOPIDÆ. An extensive family of Homoptera, comprising several species of singular insects, many of which are tropical. The head is of small or moderate size, with the face broad, the eyes lateral, the antennæ inserted in the middle or lower part of the face; the pronotum short and three-jointed; the prothorax very variable in form and size, and in the sub-family *Cercopidae* being the portion of the body which assumes the remarkable forms above alluded to. The fore-wings differ in their consistence, but the majority have them strongly veined, forming cells closed before reaching the extremity of the wing. The hind tibia vary in structure, being in some nearly simple; in others, furnished with a few strong spurs; and in many being triangular or quadrangular, each angle throwing out strong spines. The abdomen of the female is furnished with a multivalve ovipositor, variable in its form in the different species. These insects are often beautifully varied in their colours; they are constantly found amongst plants, and on trees, upon the juices of which they subsist, in all their states. One of the best known insects in this family is the *Aphrophora spumaria*, which frequents garden plants, the larva and pupa investing themselves with a frothy excrementitious secretion. [See FRUGIVORÆ.]

CERCOPITHECUS. [See MONKEY.]

CEREOPSIS. A genus of Palmipede birds that frequent the coasts in New Holland. The *Cereopsis Novæ Hollandiæ* is about the

NEW HOLLAND CEREOPSIS.
(CEREOPSIS NOVE HOLLANDIÆ.)

size of a common goose, and resembles it in its general appearance, with the exception of the length of the legs, which are from two feet

and a half to three feet. Its plumage is of a dingy grey, deeper on the upper than on the under parts. On the top of the head is a large patch of dull white; and the quill-feathers both of the wings and tail are dusky black. The naked extremity of the bill is black; the broadly expanded cere, light straw colour; the naked part of the legs, reddish orange; and the toes, together with their web and claws, black. It has a deep, hoarse, clanging voice; its usual weight is from seven to ten pounds; and its flesh is considered excellent. It is now exceedingly common in aviaries. In the Gardens of the Zoological Society we have been often struck with the grallatorial appearance possessed by this pleasing Australian Cere-faced Goose. Both the genus and species were first described by Dr. Latham.

CERITHIUM. A genus of Mollusca, chiefly inhabiting the Indian and Pacific Oceans. There is a veil on the head of the animal, two distant tentacula, having the eyes at the side, and a round, horny tuberculum. The shell (which is often also found in a fossil state) has a turriculated spire, an oval aperture, and a short but distinct canal curved to the left and backwards. There are very many species, most of which are in the collection of the British Museum.

CERTHIA. [See CREEPER.]

CERTHIADÆ. A family of Tenuirostral or slender-billed Passerine birds, commonly known by the name of *Creepers*. They are birds which for the most part are adapted to live upon the trunks and branches of trees, and to feed upon insects which infest the bark. The form of the bill varies in different species; being long and slender in some; short and stout, and capable of penetrating very hard substances, in others. These birds cling by their feet to the perpendicular surface of trees, resting upon the stiff quills of their tails; and creep from the base to the summit of the stem, with short jerking movements, searching every crevice as they ascend. Several species are described under the word CREEPER.

CERURA. A genus of Bombyceidous Moths, of which there are several species; one of the best known is the

CERURA VINULA, or PUSS MOTH. This delicately marked, and at the same time common Moth, varies from two and a half to three and a half inches in the expanse of its wings, which are of a milky-white or pale ash colour; with a transverse row of black spots, near the base, succeeded by a rather more cinereous-coloured bar, edged on both sides with black spots. Then follow in the discoidal cell three curved dusky stripes, which run in arches to the hind margin of the wing. Beyond this are two rows of blackish, very strongly dentate waves; several dark, wedge-like streaks appearing between the veins along the outer margin of the wing. The hind wings are white, but more ashy in the female, with the margin spotted with dusky. Thorax

ashy, spotted with black; abdomen white, with dusky marks. There are several varieties, in which the ground colour of the body and the markings of the wings are

PUSS-MOTH.—(CERURA VINULA.)

more or less intense. The Caterpillar is green, with a reddish head; the back dull lilac, separated from the green colour by an angulated white stripe. Its most striking peculiarity is the possession of two appendages, which, when the creature is disturbed, it pushes out sometimes to a considerable length. The Caterpillar, doubtless, in this way of expressing defiance, alarms some of its enemies; and any one not accustomed to

CATERPILLAR OF PUSS MOTH

insect-studies, would "look twice" before he ventured to touch what *would seem* a beautifully coloured and strange looking "grub," armed with two "weapons" of unknown powers. When full fed it encloses itself in a cocoon formed of chips of wood agglutinated together so firmly that it is difficult to cut it with a knife. It feeds on the willow, poplar, &c. in August, and the moth makes its appearance early in the following summer.

There are other British species of the genus, smaller in size, but more delicately marked; these are all figured in the very elegant British Moths and their transformations of Mr. Humpheys, the descriptions of which were compiled by Mr. Westwood.

CERVIDÆ. The Deer tribe; a group or family of Ruminantia, distinguished by the possession of bony deciduous horns, covered with soft skin, instead of with horny matter, and termed antlers. They are spread very extensively over the globe, each quarter having its own peculiar species, celebrated either for vigour, beauty, or speed, or for all these qualities combined.

CERVUS. [See DEER.]

CESTRACION. A genus of Sharks, found in New Holland; characterized by having

from their nests when about ten days old, and brought up with facility; but in England they are seldom kept in cages, as their song is thought to possess no variety, and they are not apt imitators of other song-birds. In Thuringia, however, it is said, there is quite a passion for keeping them, and they accordingly fetch high prices there.

Let us not suppose, however, that the Chaffinch is without a friendly advocate in this country. That he is esteemed by at least one person, and that person a naturalist of no mean calibre, the following extract from the Ornithological Essays of Mr. Waterton afford undoubted evidence:—"Amongst all the pretty warblers," says he, "which flit from bush to bush before me, as I wander through the flowery fields, next to poor cock robin, the chaffinch is my favourite bird. I see him almost at every step. He is in the fruit and forest trees, and in the lowly hawthorn: he is on the house-top, and on the ground close to your feet. You may observe him on the stack-bar, and on the dunglull; on the king's highway, in the fallow field, in the meadow, in the pasture, and by the margin of the stream. If his little pilferings on the beds of early radishes alarm you for the return of the kitchen garden, think, I pray you, how many thousands of seeds he consumes, which otherwise would be carried by the wind into your choicest quarters of cultivation, and would spring up there, most sadly to your cost. Think again of his continual services at your barn door, where he lives throughout the winter, chiefly on the unprofitable seeds, which would cause you endless trouble were they allowed to lie in the straw and to be carried out with it into the land, on the approach of spring.

"His nest is a paragon of perfection. He attaches lichen to the outside of it, by means of the spider's slender web. In the year 1807, when I was on a plantation in Guiana, I saw the humming-bird making use of the spider's web in its nidification; and then the thought struck me that our chaffinch might probably make use of it too. On my return to Europe, I watched a chaffinch busy at its nest: it left it, and flew to an old wall, took a cobweb from it, then conveyed it to its nest, and interwove it with the lichen on the outside of it. Four or five eggs are the usual number which the chaffinch's nest contains; and sometimes only three. The thorn, and most of the evergreen shrubs, the sprouts on the boles of forest trees, the woodbine, the whin, the wild rose, and occasionally the bramble, are this bird's favourite places for nidification. Like all its congeners, it never covers its eggs on retiring from the nest, for its young are hatched blind. There is something peculiarly pleasing to me in the song of this bird. Perhaps association of ideas may add a trifle to the value of its melody; for when I hear the first note of the chaffinch, I know that winter is on the eve of his departure, and that sunshine and fine weather are not far off. * * * The chaffinch never sings when on the wing; but it warbles incessantly on the trees, and on the hedge-

rows, from the early part of February to the second week in July; and then (if the bird be in a state of freedom) its song entirely ceases. You may hear the thrush, the lark, the robin, and the wren, sing from time to time in the dreary months of winter; but you will never, by any chance, have one single note of melody from the chaffinch. Its powers of song have sunk into a deep and long lasting trance, not to be roused by any casualty whatever. All that remains of its voice, lately so sweet and so exhilarating, is the shrill and well-known monotonous call, which becomes remarkably distinct and frequent whenever the cat, the owl, the weasel, or the fox are seen to be on the move.

"Sad and mournful is the fate which awaits this harmless songster in Belgium and in Holland, and in other kingdoms of the Continent. In your visit to the towns in these countries, you see it outside the window, a lonely prisoner in a wooden cage, which is scarcely large enough to allow it to turn round upon its perch. It no longer enjoys the light of day. Its eyes have been seared with a red-hot iron, in order to increase its powers of song, which, unfortunately for the cause of humanity, are supposed to be heightened and prolonged far beyond their ordinary duration by this barbarous process. Poor chaffinches, poor choristers, poor little sufferers! My heart aches as I pass along the streets, and listen to your plaintive notes. At all hours of the day we may hear these helpless captives singing (as far as we can judge) in apparent ecstasy. I would fain hope that these pretty prisoners, so woe-begone, and so steeped in sorrow, to the eye of him who knows their sad story, may have no recollection of those days when they poured forth their wild notes in the woods, free as air, 'the happiest of the happy.' Did they remember the hour when the hand of man so cruelly deprived them both of liberty and eyesight, we should say that they would pine in anguish, and sink down at last, a certain prey to grief and melancholy. * * * How the song of birds is involved in mystery! mystery probably never to be explained. Whilst sauntering up and down the Continent in the blooming month of May, we hear the frequent warbling of the chaffinch; and then we fancy he is singing solely to beguile the incubation of his female, sitting on her nest in a bush close at hand. But on returning to the town, we notice another little chaffinch, often in some wretched alley, a prisoner with the loss of both its eyes, and singing nevertheless as though its little throat would burst. Does this blind captive pour forth its melody in order to soothe its sorrows? Has Omnipotence kindly endowed the chaffinch with vocal faculties, which at one time may be employed to support it in distress, and at another time to add to its social enjoyments? What answer shall we make? We know not what to say. But be it as it will, I would not put out the eyes of the poor chaffinch, though by doing so I might render its melody ten times sweeter than that of the sweet nightingale itself. O that the potentate, in

whose dominions this little bird is doomed to such a cruel fate, would pass an edict to forbid the perpetration of the barbarous deed! Then would I exclaim, O king of men, thy act is worthy of a royal heart. That kind Being, who is a friend to the friendless, shall recompense thee for this."

CHALCIDÆ. A family of Lizards, long and serpent-like in form, and gradually presenting us with a transition from one to the other class of reptiles. The body is usually cylindrical, and extremely elongated; sometimes destitute of limbs, and mostly with the limbs only a little developed, or merely rudimentary.

For descriptions of the species (eighteen in number, and all in the British Museum), see the very admirable descriptive catalogue of the Lizards in the Museum Collection, by John Edw. Gray, Esq., F.R.S., published in 1845, in 289 closely printed pages, wherein all the species are well characterized.

CHALCIDIDÆ. A family of Hymenopterous insects, composed of a great number of parasitic species, distinguished generally by their very minute size, and many of them displaying splendid metallic colours. So exceedingly minute are some that they are reared within the eggs of other insects, but the majority infest other larvæ or pupæ. Many kinds of insect are subject to them, but they are mostly destructive to the various Lepidoptera; and there are some species, especially those having the ovipositor long and exerted, which deposit their eggs in various kinds of galls, formed by *Cynipidæ*, &c.; their progeny attacking and subsisting upon the larvæ inclosed within.

Mr. Haliday and Mr. F. Walker, F.L.S., have studied this very extensive family of insects. The latter has published a monograph of them; and there are many very beautifully engraved plates, executed by Mr. Ingall, of the Bank of England, in the "Entomologist Magazine" and the "Entomologist" of Mr. Newman. There is a large collection of them in the British Museum. Mr. Darwin brought home many from the voyage of H.M.S. Beagle; Mr. E. Doubleday found many new species during his travels in N. America; while, even in high latitudes, Mr. George Barnston, now of Tadoussac, found undescribed species of these minute insects—

"The green myriads in the peopled grass."

CHAMA. A genus of large bivalve shells, the characters of which are,—that they are commonly smooth, though in some places a little rugose; and in a few species there are numerous spines. The valves of the shell are equal, elate, and convex; and the mouth gapes, as in the oyster. The *Chama gigas* or Giant Chama, is the largest and heaviest shell yet discovered. It is found in the Indian Ocean. "Many enormous cockles" (*Chama gigas*), Captain Flinders observes, "were scattered upon different parts of the reef. At low water, this cockle seems most commonly to lie half open; but frequently closes with much noise; and the water within

the shells then spouts up in a stream, three or four feet high: it was from this noise and the spouting of the water that we discovered them, for in other respects they were scarcely to be distinguished from the coral rock. A number of these cockles were taken on board the ship, and stewed in the coppers; but they were too rank to be agreeable food, and were eaten by few." It is also called *Tridacna*. We have seen an immense pair in the church of St. Sulpice in Paris, where they serve to hold "holy water."

CHAMELEON. A lizard-like Reptile, whose peculiar faculty of changing colour has for ages amused the uninformed, and furnished matter of speculation to the philosopher. The species included in the *Chameleontidæ*, or chameleon-tribe, are distinguished by several very remarkable peculiarities. Their bodies are much compressed, or flattened sideways; and the back is surmounted by a sharp ridge. Two of the toes

CHAMELEON.—(CHAMELEO AFRICANUS.)

are directed backwards, opposing the three anterior ones; and the tail is prehensile. The tongue is a hollow tube, with a swollen fleshy extremity; and it is capable of being darted out instantaneously to a great distance, and of being as rapidly drawn in. This organ is furnished with a glutinous saliva; by which the insect prey that serve for the support of these extraordinary reptiles are attached to it. The eyes of the Chameleon are capable of being moved independently of each other; and they are constantly covered with a sort of eyelid, in which there is a small aperture corresponding with the pupil. It is a creature of a harmless nature, feeding on insects, and is capable of enduring a long abstinence; hence arose the popular idea of the Chameleon being nourished by air alone. It is found in many parts of the world, and particularly in India and Africa: it is also sometimes seen in the warmer parts of Spain and Portugal.

The cause of the different changes of colour which the Chameleon undergoes is not even yet well understood. It is said that "the rete mucosum, or coloured layer of the skin, contains two kinds of pigment, situated in different layers; the deeper-seated layer is of a deep green or violet red colour, the superficial pigment is of a greyish colour; the deep-seated pigment is contained in branched cavities, and is moveable, producing by its partial accumulation and varying proportions with the superficial layer the changes of colour for which the Chameleon has in all ages been remarkable." Dr. Shaw thus writes: "The general or usual

changes of colour in the Chameleon, so far as I have been able to ascertain from my own observation of such as have been brought into this country in a living state, are from a bluish ash-colour (its natural tinge) to a green and sometimes yellowish colour, spotted unequally with red. If the animal be exposed to a full sunshine, the unilluminated side generally appears, within the space of some minutes, of a pale yellow, with large roundish patches or spots of red-brown. On reversing the situation of the animal the same change takes place in an opposite direction; the side which was before in the shade now becoming either brown or ash-colour, while the other side becomes yellow and red; but these changes are subject to much variety both as to intensity of colours and disposition of spots."

Chameleons are all exceedingly slow, dull, and torpid; often remaining in the same position for many hours together, or traversing the twigs and branches of trees in a slow and cautious manner, with the aid of the grasping powers of the feet and tail. The skin is composed of small granular scales; the lungs are large, and are connected (as in birds) with air-cells that lie among the muscles and beneath the skin; hence the appearance of the animal varies greatly; for, according as these cavities are full or empty, it appears either full and bloated, or lean and shrunken.

CHAMOIS. (*Antilope rupicapra*. Pallas. *Rupicapra tragus*. Gray.) A well-known species of the genus ANTELOPE (to which article we refer the reader); but it being the only animal of Western Europe that partakes in any very considerable degree of the characters belonging to the *Antilopidae*, we have thought it desirable to describe it separately, under its popular name. The Chamois is found only in high mountainous regions, in small flocks or families, where they feed on the highest cliffs

CHAMOIS—(ANTILOPE RUPICAPRA.)

and precipices affording vegetation, which are almost inaccessible to man. Their sight, hearing, and smell are so acute, and they are so exceedingly shy, that it is only by the greatest patience and skill that the hunter can approach near enough to shoot them; they are likewise so swift and leap with

such vigour and sureness of foot, that to overtake them in a fair chase is next to impossible; hence the Chamois hunters of the Alps are obliged to encounter the greatest perils in pursuit of this favourite game.

The Chamois is a little more than three feet in length, and two feet in height; its head resembles that of the common goat, but the nostrils are not so large, nor the upper lip so prominent. The whole body is covered with long hair, varying with the seasons, being of a deep brown in winter, of a brown fawn colour in summer, and slightly mixed with grey in spring. The head is of a pale yellow colour, excepting a black brown band, which commences near the nose, and ends at the base of the horns and ears, after encircling the eyes; the tail is short and black; and the edges of the hips and inside of the thighs and ears alone white. The horns are about six or seven inches long, and are nearly parallel throughout: the face is straight; the ears small, erect, and pointed; and there is neither muzzle nor beard. The hoofs are concave beneath, and terminate by a projecting edge, especially on the outside. The colours of both sexes are the same, but the females are rather smaller than the males. The kids are of a deep yellowish brown colour, having the under jaw, both sides of the head, and the throat white; with similar dark bands as the adult, beginning at the corners of the mouth, surrounding the eye, and ending at the forehead. One or two are usually produced at a birth. Their flesh is considered a very superior article of food; and their skin is wrought into a soft, pliable leather, well-known by the name of the animal furnishing it. Their food consists of mountain herbs and flowers, and the tender shoots of shrubs; and it is observed that they seldom drink, and are extremely fond of salt. The father of the present Earl of Derby had several Chamois in his noble menagerie at Knowsley. We saw two young species in London some time ago, which were on their way to his Lordship's. They were sweet, gentle-looking creatures, and were by no means shy.

CHANK SHELLS. The name given to one or more species of shells of the genus *Dolium*. These shells (says Mr. McCulloch) are fished up by divers in the Gulf of Manar on the coast opposite Jaffnapatam, in Ceylon, in about two fathoms water; and at Travancore, Juticoreen, and other places. Large fossil beds of Chanks have also been found. They are of a spiral shape, and form a considerable article of trade in India, where they are in extensive demand all over the country. They are sawn into narrow rings or bracelets, and are worn as ornaments for the arms, legs, fingers, &c. by the Hindoo women; many of them are also buried with the bodies of opulent and distinguished persons. Those which, from being taken with the fish, are called green Chanks, are most in demand. The white Chank which is the shell thrown upon the beach by strong tides, having lost its gloss and consistency, is not worth the freight up to Calcutta. The value of the green Chank, depends upon its

size. A Chank opening to the right, called in Calcutta the right-handed Chank, is so highly prized, as sometimes to sell for 400, or 500, or even 1000 rupees.

CHANNEL-BILL. (*Scolothrips*.) A genus of Scansorial birds found in New Holland, &c. [See SCOTTHORS.]

CHARADRIADÆ. A family of Wading birds, or *Grallatores*, including the British Plover and allied species. [See PLOVER.]

CHARADRIUS. [See PLOVER.]

CHARR. (*Salmo salvelinus*.) A fish belonging to the family *Salmonidae*, which inhabits the lakes of Scotland, Wales, and the north of England, as well as those of the bolder and more mountainous parts of Europe; showing a strong predilection for clear

CHARR.—(*SALMO SALVELINUS*.)

and pure waters, and being seldom known to wander into running streams, except their bottoms are similar to those of its native lakes. The body is longer and more slender than that of the trout; the back is of an olive colour, speckled with whitish spots; the belly is generally red; the scales are very small, and the lateral lines are straight. The mouth is wide; the jaws are nearly equal; the lower parts of the fins are of a vermillion dye; and the gills are quadruple. Although the Charr is very scarce in this country, it occurs in many of the lakes of Cumberland, Westmoreland, and Lancashire; and its flesh is held in high estimation.

CHATTERERS. (*Ampelidæ*.) The Chatterers are a family of Passerine birds (scarcely all of whom are natives of America), subsisting on fruits and berries; but as the generality of them reside far from the habitations of man, few opportunities occur of becoming fully acquainted with their habits, &c. The only species found in Europe is the Bohemian Chatterer, or Waxwing (*Bombicillæ garrula*). [See WAXWING.]

The **PURPLE-BREASTED CHATTERER** (*Ampelis cotinga*.) inhabits Brazil. It is about nine inches in length; beak black; the head, all the upper parts of the body, and wing-coverts of a splendid glossy blue; the greater coverts, wings, and tail black; the throat and fore part of the neck purple, varied with three or four patches of bright scarlet; breast with a blue, and sometimes also a scarlet band. The female has all the upper parts of the body of a beautiful blue, and the throat, neck, and breast are purple. This and an allied species are often called *Pompador* Chatterers, from having been introduced into Europe by the

extravagant, thoughtless, and ambitious mistress of Louis XV. A fine series of these birds may be seen in the noble collection of birds in the British Museum.

The **RED CHATTERER** (*Ampelis carnifex*.) inhabits Guiana and many other parts of South America. The head is crested, and, with the lower part of the back and belly, rump, thighs, and vent, is of a bright crimson; the rest of the plumage is of a dull red, with the tips of the feathers dusky: the tail is crimson, with the tip black; the legs a dirty yellow. Its length is about seven inches.

CHEGOE, or CHIGOE. (*Pulex penetrans*.) A small and troublesome Aptèrous insect of the order *Aphaniptera*, of a black colour, which penetrates the flesh, and will, if neglected, produce malignant ulcers. It is a native of South America and the West India islands. It is, in fact, a very small flea, peculiar to warm climates, and dangerous as well as troublesome to those whom they attack. But our readers shall see what that entertaining naturalist, Waterton, has said upon the subject:—"This apparently insignificant insect far outdoes the bug in the exercise of its noxious qualities. The bug attacks you in an open manner, makes a hearty meal, and then retires to enjoy it; but the Chegoe commences its operations upon you so gently, that they are scarcely felt; and it terminates them in a way that calls for your most serious attention. In a word, it approaches you with such insinuating address, that you absolutely feel a kind of gratification at the very time it is adopting measures which will infallibly end in your certain torment. Soon after the Chegoe has entered your skin, you experience a pleasant itching kind of sensation, by which you begin to suspect that all is not right; and, on taking a nearer view of the part, you perceive that the skin is somewhat discoloured. I know it is supposed by some people, that the accounts concerning the Chegoe have been much exaggerated. I am not of this way of thinking, for I myself have smarted under its attacks; and I have minutely inspected the foot of a Negro, which was a mass of ulcers, formed entirely by the neglected ravages of the Chegoe.

"Not content with merely paying you a visit, and then taking itself off again, as is the custom of most insects, this insidious miner contrives to work its way quite under your skin, and there remains to rear a numerous progeny. I once had the curiosity to watch the movements of a Chegoe on the back of my hand, a part not usually selected by it to form a settlement. It worked its way pretty rapidly for so small an insect. In half an hour it had bored quite through the skin, and was completely out of sight. Not wishing to encourage its intended colony, 'Avast, there! my good little fellow,' said I; 'we must part company without loss of time. I cannot afford to keep you, and a numerous family, for nothing; you would soon eat me out of house and home.' On saying this, I applied the point of my pen-knife to the place where the Chegoe had

entered, and turned it loose upon the world again.

"In the plantations of Guiana there is generally an old negress, known by the name of Granny, a kind of 'Junonis anus,' who loiters about the negro yard, and is supposed to take charge of the little negroes who are too young to work. Towards the close of day, you will sometimes hear some of the most dismal cries of woe coming from that quarter. Old Granny is then at work, grubbing the Chegoe nests out of the feet of the sable urchins, and filling the holes with lime-juice and Cayenne pepper. This searching compound has two duties to perform; first, it causes death to any remaining Chegoe in the hole; and, secondly, it acts as a kind of birch-rod to the unruly brats, by which they are warned, to their cost, not to conceal their Chegoes in future: for, afraid of encountering old Granny's tomahawk, many of them prefer to let the Chegoes riot in their flesh, rather than come under her dissecting hand." In this strain our amusing "Wanderer" continues to recount the Chegoes' annoyances; but our want of space warns us to desist from indulging in a longer extract, and we conclude by observing, that, as these insects have a decided predilection for the toes, the most effectual way to prevent their attacks, is to wear thick stockings, and to bathe the feet often, particularly in sea-water.

CHEIROGALEUS. A genus of Mammalia belonging to the order *Quadrumania*, allied to the *Galagos*. They retain the whole of their inferior incisors during life; the head is round; the nose and muzzle are short; the lips are furnished with *vibrissæ*; the ears are short and oval; the eyes are

BANDED LEMUR.—(CHEIROGALEUS MEDIUS.)

large, and close to each other; the toe-nails are compressed, somewhat clawlike; while the tail is long, bushy, and cylindrical. There are two or three species of these singular Mammalia known, all of which come from Madagascar. The species figured is called *Cheirogaleus medius*.

CHEROMYS. [See AYE-AYE.]

CHEIROPTERA. The scientific name of an order of Mammalia, having the faculty of sustained flight; being characterized by having the anterior extremities so formed as to serve the office of wings, the fingers being extremely long, and connected together by an extended membrane. This power of continued flight, so contrary to the general habits of mammiferous animals, is obtained by the structure of the anterior extremities, the fingers of the fore-hand (or

claw) being greatly lengthened; between them is extended a thin membrane, which is continued from the anterior to the hinder extremities, and, in most Bats, is also continued between the hind legs, and it embraces the tail where this member is present. The food of most Bats is insects, which they are incessantly pursuing in their rapid flight; in all of these the membrane is extended between the hind legs, which enables the Bat to turn rapidly in pursuit of its prey. Some Bats, however, feed principally on fruit,

SKELTON OF A BAT

and in these the hind legs are free. They all possess four large canine teeth, but the grinders vary in number, the smallest number being on each side, three in each jaw, and the largest five above and six below, or vice versa. The incisors also vary, the smallest number being two above and two below, and the largest number four above and six below. The order *Cheiroptera* contains only one division, the *Vespertilionidae*. The flying Foxes, (*Galeopithecus*) being now very properly classed among the *Quadrumania*. Bats, then, are divided into two families; the first of which, *Istiotophori*, are characterized by the peculiar structure of the nose, the skin of which is expanded into leaf-like appendages, which are supposed to increase their power of smell; the second family, *Anistiotophori*, have the nose simple. The first family is divided into two sub-families; the first, *Phyllostomatina*, having the nose-leaf simple, and the second, *Rhinolophina*, in which it is complicated. The second family is divided into three sub-families; the first, *Vespertilionina*, in which the wings are wide and extended, the head long, and there is only a single phalanx or joint to the fore-finger; the second, *Noctilionina*, having the wings long and straight, head short and obtuse, and there are two phalanges on the fore-finger; and the third, *Pteropina*, in which the wings are rounded, the head long, and having three phalanges on the fore-finger. There are seventeen British species of Bats: two belong to the family *Rhinolophina*, the greater and lesser Horse-shoe Bat; but neither of them are very common. The remaining fifteen belong to the family *Vespertilionina*, twelve being included in the genus *Vespertilio*, the largest of which is the *V. Murinus* or Mouse-coloured Bat, the extent of the wings being fifteen inches; this species is very rare. The common Bat is the *Pipistrellus* (*V.*

Pipistrellus); the "Common Bat" of the Continent (*V. Murinus*) was long supposed to be our "Common Bat;" but this is now found to be an error. Of the remaining species, two are the most beautiful found in this country, the long-eared Bat, and the lesser long-eared Bat, belonging to the genus *Plecotus*, and the other is the *Barbastelle*. [See BAT and VAMPIRE BAT.]

CHELIFER. A genus of Arachnidæ, belonging to the family called *Pseudo-scorpiones*. Their bodies are oval, and they have the palpi elongated like arms, with a claw-like hand with two fingers; eight legs, all equal, and terminated by two ungues. They resemble small scorpions deprived of tails. The body is flattened, with the thorax nearly square, and having one or two eyes on each side. They run quickly, and often sideways like crabs. Two or three species of this and the closely allied genus *Obisium* are found in this country.

CHELONIA. An order of Reptiles, including the Tortoises and Turtles; characterized by the body being inclosed between a double shield or shell, from which the head, tail, and limbs are protruded. The animals composing this order vary considerably in those details of their structure which adapt them to different habits of life; some of them being adapted to reside exclusively upon the solid ground, and others to dwell amidst marshes, the muddy banks of rivers, &c. The LAND TORTOISES (*Testudinidae*) have a bulged carapace, sustained by a bony skeleton wholly solid, and ankylosed for the greater part to the lateral edges of the breast-plate; their legs are truncated, with very short toes connected almost to the nails, and are capable, together with the head, of being completely withdrawn into the armour. In the MARSH and RIVER TORTOISES (*Emydæ*) the toes are divided and webbed, so as to increase the extent of surface; and in the TURTLES (*Chelonidae*) they are extended into large undivided paddles, by which they can propel themselves rapidly through the water. J. E. Gray, F.R.S., and Professor Bell have published monographs of this order. [See TORTOISE and TURTLE.]

CHELURA. The name applied to a genus of small Amphipodous Crustacea, first found at Trieste by Dr. Philippi, who has described a species which he calls *C. terebrans*, from its habit of boring into wood-

CHELURA TEREBRANS

work in sea water. This species, or a very closely allied one, has been found at Ardrossan, in Ayrshire, by Major Martin, and in Duhlin Bay, Ireland, by Dr. Allman and

Mr. Thompson. It may prove nearly as destructive as the *Limnoria terebrans* [which see].

CHENALOPEX, or EGYPTIAN GOOSE. A genus of palmiped birds, allied to the Bernacle Geese, but distinguished by the length of its legs, and the small spur on the shoulder of the wing. The only known species (*Chenalopex Egyptiaca*) is often figured on the

EGYPTIAN GOOSE
(CHENALOPEX EGYPTIACA)

Egyptian monuments: it is a very common bird in aviaries, where it proves very attractive by its pretty colouring, elegant form, and the ease with which it is kept in confinement. It is a native of the South of Europe, abounding in Sicily, for example; and in N. Africa it is an abundant species, especially in the Valley of the Nile.

CHERMES. A genus of four-winged insects, which, like those of the genus *Aphis*, are found on the leaves, young shoots, and bark of various trees and vegetables. They derive their particular distinctions from the plants or trees on which they feed; as the ash, alder, elm, box, willow, nettle, &c. The abdomen is pointed, and the legs are formed for leaping. In their larva state many of them appear coated, especially on the hind part of the body, with a flocculent or filamentous clammy substance, of a white colour, which exudes from their pores.

CHEUCAU. (*Pteroptochos rubicula.*) This curious bird frequents the most gloomy and retired spots within the damp forests of the islands forming the Chonos archipelago. Sometimes, although its cry may be heard close at hand, let a person watch ever so attentively, he will not see the Cheucau; at other times, let him stand motionless, and the red-breasted little bird will approach within a few feet, in the most familiar manner. It then busily hops about the entangled mass of rotting canes and branches, with its little tail cocked upwards. Mr. Darwin opened the gizzard of some specimens: it was very muscular, and contained hard seeds, buds of plants, and vegetable fibres, mixed with small stones. The Cheucau is held in superstitious fear by the Chilotans, on account

of its strange and varied cries.—*Darwin's Journal*. [See BARKING-BIRD.]

CHEVALIER. (*Totanus glottis*.) This Gallinularian bird, which is called by some naturalists the Greenshank, and by others the Green-legged Horseman, is about twelve inches in length, and stands very high on its legs. The bill is long, reddish near the tip, and black near the base; in summer the top of its head and nape are longitudinally rayed with deep black and white; the forehead, throat, fore part of the neck, breast, upper part of the belly and the sides are white, sprinkled with oval dusky spots; the rest of the under parts are pure white, except the under tail-coverts, which have the feathers spotted with black in the direction of the shafts: the greater wing-coverts, and the long feathers which protect the quills, are of a reddish grey, spotted with black; the rest of the coverts are edged with white, which is followed by a band of brown: the two intermediate tail-feathers are ash-coloured, with transverse brown zig-zag stripes. It frequents lakes, meadows, and the margins of rivers; and its flesh is very delicate and well-flavoured.

CHEVROTAIN. [See MUSK DEER.]

CHIOGNATHA. The first division of *Myriapoda*. The body is crustaceous, and often cylindrical, the antennæ rather thickened at the tips: two thick mandibles without palpi, distinctly divided into two portions; legs very short, and always terminated by a single claw. They crawl very slowly, or rather glide along, rolling themselves into a spire or ball. The first segment of the body, and in some also the second, is largest, and represents a corselet or small shield. It is only at the fourth, fifth, or sixth segment, in different species, that the duplication of the legs commences; and the two or three terminal segments are destitute of feet. On this family and the following, the late George Newport, F.R.S., published valuable monographs in the Transactions of the Linnæan Society. [See IULUS and CENTIPEDE.]

CHILOPOLA. A division of the class *Myriapoda*. They are characterized by antennæ thick at the base, and gradually growing slender towards the apex; the mouth consists of two mandibles, which are furnished with a palpiiform process, and provided at the apex with numerous little denticulations; covering these is an upper and an under lip; above which are two palpi, resembling legs by being terminated by a pointed claw; and covering this under lip is an organ furnished with two lateral processes, each of which is terminated by a large bent claw, through the under part of which a poisonous liquid is said to be ejected. The body is somewhat flattened, composed of numerous segments, defended by plates of a horny substance, and each segment generally furnished with a pair of legs. In hot climates they grow very large, and, from their venomous bite, some of them are truly formidable. They conceal themselves under stones and fallen trees, and are all found in rotten wood. They are nocturnal in their habits, very

active, and some emit a phosphoric light. [See SCOLOPENDRA; CENTIPEDE, &c.]

CHIMERA. There are two species of this very singular kind of Chondropterygious fish, the Northern and the Southern Chimera; each named after the ocean it inhabits.

NORTHERN CHIMERA.—(*C. BOREALIS*.)

The NORTHERN CHIMERA (*Chimera Borealis*), generally abides in the deepest recesses of the sea, and is supposed to prey on the smaller fishes, as well as on the various sorts of Mollusca and Testacea. Its usual length is from three to four feet; the body is long, compressed, and gradually tapering towards the tail, which is continued into a long and slender filament; the head is very large and thick, rising up in front into a kind of pyramidal form; and at the top of the head, in the male fish, is a short upright process resembling a tuft. The mouth, placed beneath, is furnished in each jaw with a pair of broad, bony laminae, notched in the margin into a resemblance of numerous teeth; while in front, both above and below, stand two large sub-triangular teeth: the upper lip is divided into five clefts; the front, from the mouth to the eyes, is marked by transverse undulations and pores; a line runs across the forehead, and is continued in a serpentine course into the lateral line, which is very strongly marked, of a whitish colour, with dark edges, and runs to the tip of the tail: the eyes are very large and bright, of a greenish colour, with silvery irides. The body above the lateral line is of a yellowish brown, and of a bright silver colour beneath it, variegated with numerous irregular spots. The fins are yellowish-brown, varied with darker shades: the first dorsal and the pectoral fins are large and subtriangular; the ventral, similarly shaped, are smaller; and at the base of each, in the males is a lengthened sub-cylindric process, roughened by numerous sharp prominences in a reversed direction. The flesh of the Chimera is coarse, and unfit to be eaten.—The SOUTHERN CHIMERA (*Chimera Australis*) is nearly of the size of the preceding species, but with the front sloping downwards, and the upper lip extended into a lengthened cartilaginous flap, bending downwards in a reversed direction beneath: general colour of the whole fish silvery, with a yellowish-brown cast on the upper parts: fins pale brown. Its manner of life is similar to that of the *Chimera Borealis* in the Northern Hemisphere.

CHIMNEY SWEEPER [MOTH]. A name given by collectors to Moths of the genus *Fumea*.

CHIMPANZEE. (*Pithecus troglodytes*.) Cuvier placed the Orang-Outang foremost in the rank of QUADRUMANA, but later natu-

ralists consider the Gorilla and Chimpanzee to approximate more nearly in their general conformation to man. [See GORILLA in SUPPLEMENT.] The Chimpanzee is an in-

CHIMPANZEE.—(PITHECUS TROGLODYTES.)

habitant of Africa, and especially of the coasts of Congo and Angola; and travellers who have visited those countries assure us that in an adult state the Chimpanzees attain the stature of man, and live in society in the woods; that they construct huts of the leaves and branches of trees, to protect themselves against the extreme heat of the sun and the violence of the rains; that they walk upright, arm themselves with clubs, and make a formidable resistance against the attacks of the largest and most powerful beasts. The body of the Chimpanzee is covered with long black hair on the head, shoulders, and back, but much thinner on the breast and belly; the arms and legs are not so disproportionate as those of the Oran-Outang, the fore-fingers not quite touching the knees when the animal stands upright. The upper part of the head is very flat, with a retiring forehead, and a prominent bony ridge over the eyebrows; the mouth is wide, the ears large, the nose flat, and the face of a blackish brown colour. There was formerly a female Chimpanzee in the Zoological Gardens, Regent's Park, supposed to be about ten years old: she was remarkably docile, and performed certain actions with much apparent rationality.

How truly has it been said, that although the gradations of Nature in the other parts of her works are minute and imperceptible, yet in the ascent from brutes to men the line is strongly drawn, well marked, and decisive! In vain the Chimpanzee or Oran-Outang may resemble Man in form, or may possess the power of imitating his actions, it still continues a wretched helpless creature; and whatever distant resemblance its internal conformation may bear to the human, its whole figure exhibits a picture sufficiently mortifying to those who pride themselves on personal appearances alone. The tongue and all the organs of voice may be the same, yet the animal is dumb; the brain may be formed in the same manner, yet the animal is destitute of reason; an evident proof, as Buffon beautifully observes, that no disposition of matter can constitute a mind; and that the body, how nicely soever constructed, is constructed in vain, when no soul is in-

fused into it for the purpose of directing its operations.

Mr. Newman furnishes the readers of the "Zoologist" (1845) with the subjoined particulars:—"A larger, stronger, and more active Chimpanzee than any previously imported, was lately consigned to Messrs. Coleman, Flockhart, and Co., from the river Nunez, near Sierra Leone. On its arrival in the London Docks I paid it a visit, and immediately communicated with Mr. Yarrell, with a view to obtaining it for the Zoological Society: the officials, however, were already on the alert, and the creature has since been purchased by the society for 300*l*. The following paragraph, which has been circulated in the London newspapers, was, I hear, penned by one of the keepers:—"It is singular that she resists every attempt to correct her, fighting with the utmost determination; every other animal, even the Orang, fears its keeper. The first day of the Chimpanzee's arrival at the Gardens, she tore out three of the strong iron bars of her cage, which have been since strengthened. A temporary nail was driven about half its length, into a piece of wood, about six inches long and three and a half square; she held the wood between her teeth, and doubling the nail backwards and forwards, broke it short off. When in a passion, she tears her hair and rolls herself on the ground violently. Her table is supplied from her keeper's, and she shares in everything and anything he has. She eats her egg with a spoon, takes her grog daily, and, 'tis said, that when on board ship she mixed the latter herself. She will lock and unlock a door or drawer; will thread any needle; she cannot be taken in by the same thing twice, and will imitate almost anything that is done before her. She is considered by Professor Owen to be about nine years old, which well agrees with all accounts of her previous life. She weighs 52 lbs.; measures 2 feet 2 inches round the chest, and is 3 feet 2 inches high; or, as she will not stand upright to be measured, probably her height is nearly 3 feet 6 inches.' On making a more careful examination of this animal in her present abode, I was particularly struck by her want of teeth. Only one incisor and a few imperfect molars appear to remain. I observed her total inability to crack a nut, a feat performed by almost every other monkey with great adroitness. Her manners now are perfectly quiet, and there is no appearance of the ferocity implied in the preceding quotation; she was gentle in the extreme, shaking hands in a very cordial manner with some children who were present, and perfectly on the alert at the sound of her name—"Susan"—when ever it was uttered. I presume the keeper imagined that details of her ferocity would give her an interest in the eyes of the public. I have observed that the captains of Margate steamers always tell their passengers that the present is the roughest passage they ever encountered; so the visitors of this gentle being are assured it is the most savage Chimpanzee. The Captain, to whose care "Susan" was entrusted, told me that in taking her meals on the passage home, she used

knife, fork, spoon, and drinking cup, with the same ease as a human being, and with whatever food she was supplied, she preferred using a fork or a spoon to convey it to her mouth, to holding it in her hands. For more than three years she had been in possession of a Mr. Campbell, who left her at perfect liberty, never subjecting her to the slightest confinement. When he received her she was quite young—a mere baby, so that her present age may be supposed four or five years, rather than eight or nine. When on board ship she entertained a great dislike to black men, who used to tease and otherwise misuse her; but with the crew generally she appeared on excellent terms, and exhibited many traits of extreme docility."

CHINA-MARK [MOTHS]. A name given by collectors to Moths of the genera *Hydro-campa* and *Margarita*.

CHINCHILLA. This little Rodent animal, so highly valued on account of its fur, is a native of South America, inhabiting the valleys in the high mountain districts, where the cold is often very severe. There are several species belonging to the natural family *Chinchillidae*, of which this animal and the *Viscacha* of the Pampas are the chief. The colour of the Chinchilla is clear grey above,

CHINCHILLA.—(C. LANGEA.)

passing into white on the under parts. It associates in numbers, and excavates burrows, in which it resides, feeding chiefly upon roots. In size and general form it much resembles the rabbit, with the exception of the tail, which turns up after the manner of a squirrel's. The fur is of a remarkably close and fine texture; and is, accordingly, much used in muff, tippets, linings to cloaks, trimmings, &c.

CHIRONOMIDÆ. A sub-family of Dipterous insects, which frequent marshy situations, and very much resemble gnats. The species are of small size and very numerous; they often assemble in immense cloud-like swarms; and the name of *Midge* is given to them.

CHITON. A genus of marine Mollusca, inhabiting multivalve shells, several species of which are found on our own coasts. They adhere to rocks and stones, in general, near low-water mark. The shell is boat-shaped, composed of about eight transverse pieces, folding over each other at their edges, and inserted into a tough ligament. They sometimes attain a large size, but do not usually exceed two inches. They have the power of rolling themselves up into a ball,

like the wood-louse. Several new species of these shells were collected in the Eastern Archipelago by Sir Edward Belcher and Mr. Adams during the voyage of H. M. S. *Samarang*; two of which, viz., *Chiton priapus*, which is described as a beautiful little bright

SCALY ARMADILLO-SHELL.
(CHITON SQUAMOSUS.)

scarlet shell enframed within a broad swollen ligament of the same striking colour; and *Chiton formosus*,—a most exquisite little species, of a bright scarlet colour, surrounded with dense tufts of white shining glassy spiculae. For a revision of this genus, see a paper by Mr. Gray, recently published. Mr. L. Reeve has published figures of many of the species in his "*Conchologia Iconica*." Mr. Cuming collected a very great number of beautiful species, many of which are in the fine collection of the British Museum; and it is to be hoped that the Government will procure for the National Museum the whole of Mr. Cuming's magnificent collection of shells.

CHLAMYDOSAURUS. A genus of Saurians, described by Mr. Gray, from a specimen discovered in Australia by the late Allan Cunningham, F.L.S., who (between the years 1818 and 1822) accompanied Capt. King's expedition as His Majesty's botanical collector for Kew Gardens. It was taken on the branch of a tree, and sent to Sir Everard Home, by whom it was deposited in the Museum of the Royal College of Surgeons. In Mr. Cunningham's Journal, it is described as a lizard of extraordinary appearance, having a curious creuated membrane, like a ruff or tippet round its neck, covering its shoulders, and when expanded, which it was enabled to do by means of transverse slender cartilages, spreading five inches in the form of an open umbrella. Its head was large, and its eyes, whilst living, rather prominent; its tongue, though bifid, was short, and appeared to be tubular. From Mr. Gray's description of the *Chlamydosaurus Kingii* (the Frilled Lizard), in the Appendix to Capt. King's Voyage, we learn that the animal was scaly; colour yellowish brown, variegated with black; head depressed, with the side erect, leaving a blunt ridge on the upper part wherein the eyes are placed. The frill arises from the hinder part of the head, is attached to the sides of the neck, and extends down to the front part of the chest, supported above by a lunate cartilage arising from the hinder dorsal part of the ear, and in the centre by a bone which extends about half its length. Each frill has four plates which converge on the under part of the chin, and fold it up on

the side, and a fifth where the two are united in the centre of the lower part of the neck. The front part of its upper edge is elegantly serrated, and the outer surface is covered with carinated scales; the inner surface being quite smooth. The scales of the back are oval; those of the lower part of the body and upper part of the legs have a short midrib, and those of the sides and joints of the limbs are minute. The body is five inches long, the tail twelve, the head nearly six, and the outer edge of the frill ten inches: the toes are long, very unequal, compressed, and scaly: the claws are hooked, and horn-coloured. This frill increases in size more in proportion than the animal's growth; in the young it does not reach to the base of the fore limbs, while in the adult it becomes much fuller, and reaches considerably beyond the axilla.

KING'S FRILLED LIZARD.
(CHLAMYDOSAURUS KINGI.)

It would seem to be not uncommon about Port Essington; and it is found in other parts of Australia. Captain George Grey (now governor of New Zealand) met with it, and gives us the following interesting notice of its habits in the first volume of his *Travels*. He says, "As we were pursuing our route in the afternoon, we fell in with a specimen of the remarkable Frilled Lizard; this animal measures about twenty-four inches from the tip of the nose to the point of its tail, and lives principally in trees, although it can run very swiftly along the ground: when not provoked or disturbed, it moves quietly about, with its frill lying back in plates upon the body; but it is very irascible, and directly it is frightened, it elevates the frill or ruff, and makes for a tree; where, if overtaken, it throws itself upon its stern, raising its head and chest as high as it can upon the fore-legs, then doubling its tail underneath the body, and displaying a very formidable set of teeth, from the concavity of its large frill, it boldly faces any opponent, biting fiercely whatever is presented to it, and even venturing so far in its rage as to fairly make a fierce charge at its enemy. We repeatedly tried the courage of this lizard, and it cer-

tainly fought bravely whenever attacked. From the animal making so much use of this frill as a covering and means of defence for its body, this is most probably one of the uses to which Nature intended the appendage should be applied. The whole animal is fulvous, obscurely varied with brown; the young being more distinctly marked with regularly waved black streaks, forming broad bands across the back, limbs, and tail."

CHLAMYPHORUS. An edentate quadruped, found in South America, in which several characters of different tribes are remarkably blended. Like the Armadillo, it has a tessellated shield, the consistence of which is between horn and leather; but instead of being firmly attached by its whole under surface to the integuments beneath, it is connected with the back only by a ridge of skin along the spine, and with the skull by two bony prominences from the forehead. In the form of its feet, its imperfect eyes, the conical shape of its snout, and its general habits, it resembles the mole. It is a native of Chili, but is so rare even there as to be regarded by the natives as a curiosity. The total length of the entire animal is five inches and a quarter. The shelly covering is composed of a series of plates of a square, rhomboidal, or cubical form, each row separated by a membranous substance, which is reflected above and beneath, over the plates: the rows include from fifteen to twenty-two plates, the shell being broadest at its posterior half, extending about one half round the body. This covering is loose throughout, except along the spine of the back and top of the head. The number of rows of plates on the back, counting from the vertex, where they commence, is twenty-four; the shell then curves suddenly downwards, so as to form a right angle with the body: this truncated surface is composed of plates, nearly similar to those of the back, and are disposed in semicircular rows; the lower margin, somewhat elliptical, has a notch in its centre, in which is attached the free portion of the tail, which curves abruptly, and runs beneath the belly parallel to the axis of the body, the extremity of the tail being depressed, so as to form a paddle. The superior semicircular margin of the truncated surface, together with the lateral margins of the shell, are beautifully fringed with silky hair.

CHLAMYPHORUS TRUNCATUS

The following points of resemblance between the skeleton of *Chlamyphorus* and that of other quadrupeds have been noticed by Mr. Yarrell:—1. Beaver (*Castor fiber*), in the form and substance of some of the bones

of the limbs, in the flattened and dilated extremity of the tail, and the elongation of the transverse processes of the lower caudal vertebrae. 2. Mole (*Talpa Europea*), in the shortness and great strength of the legs, and

SKELTON OF CHLAMYPHORUS TRUNCATUS.

in the articulation of the claws to the first phalanges of the toes. 3. Sloth (*Bradypus tridactylus*), in the form of the teeth, and in the acute descending process of the zygoma. 4. Armadillo (*Dasypus*), in the coat of mail, in the peculiar ossification of the cervical vertebrae, in possessing the sesamoid bones of the feet, and in the general form of the bones, except those of the pelvis. 5. *Orycteropus Capensis* and *Myrmecophaga jubata*, in some of the bones. 6. *Echidna* and *Ornithorhynchus*, in the form of the first bone of the sternum, and in the bony articulations as well as the dilated connecting plates of the true and false ribs. 7. and 8. *Ruminantia* and *Pachydermata*, in the form of the lower jaw, &c. The unique points in its osteological structure appear to be the form of the head and the open pelvis. Dr. Buckland considers *Chlamyphorus* one of the nearest approximations to *Megatherium*, particularly in regard to its coat of mail, and in the adaptation of the animal for digging.

Dr. Harlan, who first described this remarkable animal, says, "We have been presented in the subject before us with a new form; an animal combining in its external configuration a mechanical arrangement of parts which characterizes, respectively, the armadillo, the sloth, and the mole; constituting in themselves, individually and separately, of all other quadrupeds, those which offer the most remarkable anatomical characters. * * * The structure of this animal, Dr. Harlan goes on to say, taken collectively, furnishes us with an example of organic structure, if not unparalleled, not surpassed in the history of animals."—*Ann. New York Lyceum*, p. 245. . .

CHOCOLATE-TIP [MOTHS]. A name given by collectors to Moths of the genus *Closteros*.

CHONDROPTERYGII. The term for one of the great classes or families of fishes; characterized by the cartilaginous nature of the spines and bones. Cuvier divides the *Chondropterygii* into two orders,—those which have their gills free, as in the generality of fishes, and those in which they are fixed.

CHÆROPOTAMUS. [See APPENDIX.]

CHOUGH (CORNISH), or RED-LEGGED CROW. (*Pyrrhocorax graculus*.) A bird somewhat taller and longer than the Jackdaw, whose habits it in many respects

resembles. Its colour is a beautiful black, glossed with blue and purple: the bill is long, curved, sharp at the tip, and of a bright orange-red; the legs are of a similar colour, with black claws. It builds on high cliffs, by the sea side, lays four or five eggs, spotted with yellow, and chiefly frequents the coasts of Cornwall, Devonshire, and Wales, though it is sometimes found on the cliffs of Dover, in Scotland, and the Hebrides. In a wild state it feeds principally on insects and berries. It is easily tamed, becomes extremely docile, and is very fond of being caressed by those to whom it shows an attachment, but its shrill notes and mischievous qualities render it sometimes a troublesome inmate. It also becomes bold and pugnacious, and presents an affront with violence and effect.

CHRYSIDIDÆ, or GOLDEN WASPS. A family of Hymenopterous insects, most of which seek the nests of other insects, wherein to deposit their eggs. They are generally distinguished by a peculiar brilliancy of colour, are very active, and are seen flying

CHRYSIS IGNITA.

about in the sunshine, settling upon old walls, palings, &c. The most common, and at the same time most beautiful British species, is the *Chrysis ignita*; it is about the size of the common window fly, and is of a rich deep blue-green colour on the head and thorax, with the abdomen of a burnished golden-copper hue.

CHRYSOCHLORIS, or CAPE MOLE. A Rodent quadruped very much resembling the mole in general structure and habits. There is no external ear, nor any appearance of the eye externally: the body is thick and short; and the claws are particularly well adapted for digging and burrowing in the earth: but it is chiefly distinguished by the splendid colours of its fur, and is the only known quadruped which exhibits anything like the metallic lustre that adorns numerous birds, fishes, and insects. The best known species (*Chrysochloris Capensis*) is, as the name implies, a native of the Cape of Good Hope.

CHRYSOMELA: CHRYSOMELIDÆ. An extensive genus and family of Coleopterous insects, generally of a small or moderate size, and frequently ornamented with the most brilliant colours, amongst which blue, green, and gold are pre-eminently conspicuous. The antennæ are moniliform, thickening towards the tip; the thorax margined; and the body ovate, oblong, or subhemispherical.—*Chrysomela Grominis* is a common but highly elegant insect, of a most vivid, but deep golden-green colour; shape extremely convex.—*Chrysomela Betulae*, found

on birch-trees, is one of the richest of the genus, being entirely of the most brilliant and beautiful grass-green. The species of the genus *Chrysomela*, and others separated therefrom, are distinguished by the possession of wings, and an oval or rounded body. Among these the *Chrysomela Populi* is one of the most common species. It is of a blue-black colour, with red elytra, tipped with black. It is found upon the willow and poplar. Its larva is of an oblong-ovate form, of a dirty greenish-white colour, with numerous black scaly spots; its meso- and metathoracic segments are furnished with two large lateral conical tubercles, and the abdominal segments have also two rows of smaller dorsal and lateral tubercles, from which, as well as from the joints of the legs and mouth, drops of a fetid fluid are emitted when the larva is alarmed. The eggs are deposited upon the leaves in clusters. The pupa is ovate, having the excuviae of the larva collected in a mass at the extremity of the body. The larva of some species of this family feed, in society, upon leaves, preserving one or more most orderly rows. Among the most elegant species found in the United States of North America (according to Dr. Harris) is the *Chrysomela scalaris* of Leconte, literally the ladder *Chrysomela*. The head, thorax, and under side of its body are dark green, the wing-covers silvery white, ornamented with small green spots on the sides, and a broad jagged stripe along the suture or inner edges; the antennae and legs are rust-red; and the wings are rose-coloured. It is a beautiful object when flying, with its silvery wing-covers embossed with green, raised up, and its rose-red wings spread out beneath them. These beetles inhabit the elm and lime trees, upon which they may be found in April, May, and June, and a second brood of them in September and October. They pass the winter in holes, and under leaves and moss. The trees on which they live are sometimes a good deal injured by them and their larvæ. The latter are hatched from eggs laid by the beetles on the leaves in the spring, and, when full grown, are about half an inch long, of a white colour, with a black line along the top of the back, and a row of small square black spots on each side of the body; the head is horny, and of an ochre-yellow colour; the body is short and very thick, the back arching upwards in the middle.

CHUB. (*Cyprinus cephalus*.) This fish is a native of many parts of Europe, and is

CHUB.—(*CYPRINUS CEPHALUS*.)

not uncommon in our own island. It frequents the deep holes of rivers, and, during the summer season, commonly lies on the

surface of the water, beneath some tree or bush. In shape the Chub rather resembles the Tench, but is of a more lengthened form, and has a larger head in proportion. It is from fourteen to eighteen inches in length; its colour silvery, with a bluish olive cast on its upper parts; the sides bluish white, passing into silvery white on the belly; the scales very large, and the lateral line nearly straight; the dorsal fin is rather small, and situated on the middle of the back; the pectoral fins are of a pale yellow; the ventral and anal fins are red; and the tail is slightly forked, and of a dull bluish-brown colour. It feeds on worms, caterpillars, grasshoppers, beetles, and other coleopterous insects which happen to fall into the water.

CICADA. The family of insects bearing the generic name *Cicada*, or *Cicadidae*, are nearly all inhabitants of tropical or the warmer temperate regions. The most common European species is the *Cicada plebeia* of Linnaeus; no insect often commemorated by the ancient poets, but generally confounded by the major part of translators with the Grasshopper. It is a native of the warmer parts of Europe, particularly of Italy and Greece; appearing in the hotter months of summer, and continuing its shrill chirping during the greatest part of the day, generally sitting among the leaves of trees. These insects proceed from eggs deposited by the

MANNAH FLY.—(*CICADA ORNI*.)

parent in and about the roots of trees, near the ground; and after having remained in the larva state nearly two years, cast their skins, and produce the complete insect.

The male Cicada produces a loud clurping note, and much has been written in praise of it by Anacreon and other ancient authors; it is certain, however, that modern ears are offended rather than pleased with its voice, which is so very strong and stridentulous that it fatigues by its incessant repetition. That a sound so piercing should proceed from so small a body may well excite our astonishment; and the curious apparatus by which it is produced has justly claimed the attention of the most celebrated investigators. They have found that it proceeds from a pair of concave membranes, seated on each side the first joints of the abdomen: the large concavities of the abdomen, immediately under the two broad lamellæ in the male insect, are also faced by a thin, pellucid, iridescent membrane, serving to increase and reverberate the sound; and a strong muscular apparatus is exerted for the purpose of moving the necessary organs.

Among the large and elegant insects in this division is the *Cicada hrenatodes*, distinguished by its shining black body, with the

divisions of the abdomen marked by numerous scarlet rings or bands; and the *Cicada viridis*, a large species, native of New Holland, of a beautiful green colour, with the transparent wings ornamented by green veins.

Cicada septendecim, or Seventeen-year Cicada. It is well remarked by Dr. Thaddeus Harris, that "the duration of life in winged insects is comparatively very short, seldom exceeding two or three weeks in extent, and in many is limited to the same number of days or hours. To increase and multiply is their principal business in this period of their existence, if not the only one, and the natural term of their life ends when this is accomplished. In their previous states, however, they often pass a much longer time, the length of which depends, in great measure, upon the nature and abundance of their food." The *harvest-flies* continue only a few weeks after their final transformation, and their only nourishment consists of vegetable juices, which they obtain by piercing the bark and leaves of plants with their beaks; and during this period they lay their eggs and then perish. They are, however, amply compensated for the shortness of their life in the winged state by the length of their previous existence, during which they are wingless and grub-like in form, and live under ground, where they obtain their food only by much labour in perforating the soil among the roots of plants, the juices of which they imbibe by suction. To meet the difficulties of their situation and the precarious supply of their food, a remarkable longevity is assigned to them; and one species has obtained the name of *Cicada septendecim*, on account of its life being protracted to the period of seventeen years. This insect, in the perfect state, is of a black colour, with transparent wings and wing-covers, the thick anterior edge and larger veins of which are orange-red, and near the tips of the latter there is a dusky zigzag line in the form of the letter W; the eyes when living are also red; the rings of the body are edged with dull orange; and the legs are of the same colour. The wings expand from two inches and a half to three inches and a quarter.

In those parts of the United States, as we are informed, which are subject to the visitation of this Cicada, it may be seen in forests of oak about the middle of June. Here such immense numbers are sometimes congregated, as to bend and even break down the limbs of the trees by their weight, and the woods resound with the din of their discordant drums from morn to eve. After pairing, the females proceed to prepare a nest for the reception of their eggs. They select, for this purpose, branches of a moderate size, which they clasp on both sides with their legs, and then bending down the piercer at an angle of about forty-five degrees, they repeatedly thrust it obliquely into the bark and wood in the direction of the fibres, at the same time putting in motion the lateral saws, and in this way detach little splinters of the wood at one end, so as to form a kind of fibrous lid or cover to the perforation. The hole is

bored obliquely to the pith; and is gradually enlarged by a repetition of the same operation, till a longitudinal fissure is formed of sufficient extent to receive from ten to twenty eggs. The side pieces of the piercer serve as a groove to convey the eggs into the nest, where they are deposited in pairs, side by side, but separated from each other by a portion of woody fibre, and they are implanted into the limb somewhat obliquely, so that one end points upwards. When two eggs have been thus placed, the insect withdraws the piercer for a moment, and then inserts it again and drops two more eggs in a line with the first, and repeats the operation till she has filled the fissure from one end to the other, upon which she removes to a little distance, and begins to make another nest to contain two more rows of eggs. She is about fifteen minutes in preparing a single nest and filling it with eggs; but it is not unusual for her to make fifteen or twenty fissures in the same limb; and one observer counted fifty nests extending along in a line, each containing fifteen or twenty eggs in two rows, and all of them apparently the work of one insect. After one limb is thus sufficiently stocked, the Cicada goes to another, and passes from limb to limb and from tree to tree, till her store, which consists of four or five hundred eggs, is exhausted. At length she becomes so weak by her incessant labours to provide for a succession of her kind, as to falter and fall in attempting to fly, and soon dies.

Although the Cicadas abound most upon the oak, they resort occasionally to other forest-trees, and even to shrubs, when impelled by the necessity for depositing their eggs, and not unfrequently commit them to fruit-trees, when the latter are in their vicinity. Indeed there seem to be no trees or shrubs that are exempted from their attacks, except those of the pine and fir tribes, and of these even the white cedar is sometimes invaded by them. The punctured limbs languish and die soon after the eggs which were placed in them are hatched; they are broken by the winds or by their own weight, and either remain hanging by the bark alone, or fall with their withered foliage to the ground. In this way orchards have suffered severely in consequence of the injurious punctures of these insects. The eggs are one twelfth of an inch long, and one sixteenth of an inch through the middle, but taper at each end to an obtuse point, and are of a pearl-white colour. The shell is so thin and delicate that the form of the included insect can be seen before the egg is hatched.

The young insect when it hurls the shell is one sixteenth of an inch long, and is of a yellowish white colour, except the eyes and the claws of the fore-legs, which are reddish; and it is covered with little hairs. In form it is somewhat grub-like, being longer in proportion than the parent insect, and is furnished with six legs, the first pair of which are very large, shaped almost like lobster-claws, and armed with strong spines beneath. On the shoulders are little prominences in the place of wings; and under the breast is a long beak for suction. These

little creatures when liberated from the shell are very lively, and their movements are nearly as quick as those of ants. After a few moments their instincts prompt them to get to the ground, but in order to reach it they do not descend the body of the tree, neither do they cast off themselves precipitately; but running to the side of the limb, they deliberately loosen their hold, and fall to the earth. The instinct which impels them thus fearlessly to precipitate themselves from the trees, from heights of which they can have formed no conception, without any experience or knowledge of the result of their adventurous leap, is still more remarkable than that which carries the gosling to the water as soon as it is hatched. In those actions, that are the result of foresight, of memory, or of experience, animals are controlled by their own reason, as in those to which they are led by the use of their ordinary senses or by the indulgence of their common appetites they may be said to be governed by the laws of their organization; but in such as arise from special and extraordinary instincts, we see the most striking proofs of that creative wisdom which has implanted in them an unerring guide, where reason, the senses, and the appetites would fail to direct them. On reaching the ground the insects immediately bury themselves in the soil, burrowing by means of their broad and strong fore-feet, which, like those of the mole, are admirably adapted for digging. They do not appear ordinarily to descend very deep into the ground, but remain where roots are most abundant. The only alteration to which they are subject during the long period of their subterranean confinement, is an increase of size, and the more complete development of the four small scale-like prominences on their backs, which represent and actually contain their future wings.

As the time of their transformation approaches, they gradually ascend towards the surface, making in their progress cylindrical passages, oftentimes very circuitous, and seldom exactly perpendicular, the sides of which are firmly cemented and varnished so as to be waterproof. When the insect has nearly approached the surface it takes up its temporary habitation till the period for its exit arrives. Here it remains during several days, ascending to the top of the hole in fine weather for the benefit of the warmth and the air, and occasionally peeping forth apparently to reconnoitre, but descending again on the occurrence of cold or wet weather. When at length a favourable moment arrives for them to come forth from their subterranean retreats, they issue from the ground in great numbers in the night, crawl up the trunks of trees, or upon any other object to which they can fasten themselves securely by their claws. After having rested awhile they prepare to cast off their skins, which, in the mean time, have become dry and of an amber colour. By repeated exertions a longitudinal rent is made in the skin of the back, and through this the included Cicada pushes its head and body, and withdraws its wings and limbs from their separate

cases, and, crawling to a little distance, it leaves its empty pupa skin, apparently entire, still fastened to the tree. At first the wing-covers and wings are very small and opaque, but, being perfectly soft and flexible, they soon stretch out to their full dimensions, and in the course of a few hours the superfluous moisture of the body evaporates, and the insect becomes strong enough to fly. During several successive nights the pupa continue to issue from the earth; above 1500 have been found to arise beneath a single apple tree, and in some places the whole surface of the soil, by their successive operations, has appeared as full of holes as a honeycomb. Within about a fortnight after their final transformation they begin to lay their eggs, and in the space of six weeks the whole generation becomes extinct. Fortunately these insects are appointed to return only at periods so distant, that vegetation often has time to recover from the injury inflicted by them. They have also many enemies, which contribute to diminish their numbers. Their eggs are eaten by birds; the young, when they first issue from the shell, are preyed upon by ants, which mount the trees to feed upon them, or destroy them when they are about to enter the ground. Blackbirds eat them when turned up by the plough in fields, and hogs are excessively fond of them, and, when suffered to go at large in the woods, root them up, and devour immense numbers just before the arrival of the period of their final transformation, when they are lodged immediately under the surface of the soil. We may mention that one species has been found in this country, where, however, it is rare; it has been called *Cicada Anglica*, but seems not to be distinct from a common European species.

CICADIDÆ. The first family of Homopterous insects, in the section TRIMERA, and corresponds with the *Cicada mannifera* of Linnaeus. It embraces the largest insects in the order, one species measuring between six and seven inches in the expanse of its wings. [See CICADA.]

CICINDELA: CICINDELIDÆ; or **TIGER BEETLES.** A genus and family of Coleopterous insects remarkable for the celebrity and vigour of their flight; characterized by the great projection of the eyes, long and sharply pointed jaws; thorax depressed and nearly square; and the legs and antennae long and slender. They are generally seen on the wing in the hottest part of the day, chiefly frequenting dry meadows, sandy plains or heaths, or the banks of rivers. One of the most striking genera is the *Manticora*, found at the Cape of Good Hope. The common **GREEN TIGER-BEETLE** (*Cicindela campestris*), one of the most common European species, is a highly beautiful insect, being of a bright grass-green, with the elytra each marked by five small, round, cream-coloured spots: the head, thorax, and limbs are of a rich gilded cast; the eyes black and prominent; the legs long and slender. The larva of this insect lives in cylindrical burrows, excavated by itself, and varying

from six inches to a foot in depth. The head is very large, and slightly concave; the jaws are curved and strong; and the

MANTICORA MAXILLOSA

body is humped near the middle of the back, at which part there are two hooked tubercles. In the process of excavation they use their jaws and feet, and load the concave back of their heads with the grains of earth which they have detached; thus loaded, they ascend backwards, resting at intervals, and fixing themselves to the inner walls of their burrow by the assistance of the two hooked tubercles on the back; and when arrived at the orifice, they jerk off their load to a distance. The Cicindela are all voracious; and when their prey comes within their reach, they rush upon it with great ferocity.

CILIOGRADA. An order of *Acalephae*, or gelatinous transparent marine animals, distinguished by their continually agitating the cilia with which their contractile bodies are provided; organs which possess the phosphorescent faculty in a very high degree. [For examples, see *Beroë*, and *Mедуза*.]

CIMEX: CIMICIDÆ. A genus and family of Hymenopterous insects, allied to *Tenthredinetae*, or *Saw-flies* (as they are com-

CIMEX VARIABILIS, AN. IT. LARVA.

monly called, from their saw-like ovipositor), comprising those species which have the antennae alike in both sexes, and terminated

by a knob or a reversed cone rounded at the tip, preceded by four or five joints, and the two subcostal nerves being contiguous without a wide intermediate space. The larvæ of these insects greatly resemble the Caterpillars of Lepidopterous insects, but have from eighteen to twenty-two feet, or only six, which distinguishes them from true caterpillars, which have from ten to sixteen feet. In order to undergo their change, they spin, either on the earth or on the plants upon which they have fed, a cocoon, in which, like the rest of the family, they remain unchanged for many months.

CIMEX. A Linnæan genus of Hemipterous insects, now subdivided into several families or sections, according to the general shape or habit of the insects, and severally named *Cimicidæ*, *Pentatomidæ*, *Cydnidæ*, *Coreidæ*, *Lygeidæ*, *Reduviidæ*, *Acanthidæ*, and *Hydrometridæ*; the two terminal joints of the antennæ of hair-like fineness; body much depressed; thorax transverse; antennæ four-jointed; labrum rather long and pointed, and when the proboscis is not in use, recurved under the head. The bed-bug (*Cimex lectularius*) may serve as a general example of this very extensive tribe. [See Bug.]

CIMOLIORNIS. [See APPENDIX.]

CINCLOSOMA. A genus of Passerine birds, belonging to the *Turdidæ* family. The species *Cinclosoma punctatum*, or Spotted Ground Thrush, inhabits Van Diemen's Land and Eastern Australia. It prefers the summits of low stony hills and rocky gullies, particularly those covered with scrubs and bushes. Its flight is very limited; but it readily evades pursuit by running over the stony surface and concealing itself among the underwood: when flushed suddenly, it rises with a loud whirring noise, like a Quail or Partridge. Its note consists of a low piping whistle. It is sold in Hobart-Town market, with Bronzings, Pigeons, and Wattle-birds, and is known there as the Ground Dove: doubtless from its terrestrial habits and its flesh being excellent eating. To its delicacy, and the large development of the pectoral muscles, and the contour of the body, resembling a Quail, Mr. Gould gives his testimony. It breeds in October and three following months. The nest, which is always placed on the ground, is a slight and rather careless structure, composed of leaves and the inner bark of trees, and is of a round, open form. The stomach of this bird, on dissection, was found to contain seeds and caterpillars, mingled with sand. Another species, *Cinclosoma castaneotus*, found near the Swann River, is a much shyer bird than the *C. punctatum*, and runs over the ground faster; its shorter toes considerably assisting its progressive motion.

CINCLUS. The Water-ouzel [which see].

CINNYRIS. CINNYRIDÆ. A genus and family of small birds, remarkable for the splendid metallic lustre of their plumage in which they rival the Humming-birds (*Trochilidæ*). All the species inhabit the

Old World; chiefly Africa and India. [See SUN-BIRD.]

CIRRIPEDIA, or CIRRIPEDES. A class of invertebrated animals, so named from the curled and ciliated branchiæ which protrude from the oval aperture of the shells. They are divided into sessile, that is, either themselves firmly united at their bases to rocks or solid masses; and pedunculated, or attached by a long peduncle or footstalk. They are closely allied to the Crustacea.

CISSITIS. A genus of Coleoptera. [See HORIARÆ.]

CISTELA; CISTELIDÆ. A genus and family of Coleopterous insects, belonging to the section *Heteromera*. They are characterized by antennæ nearly filiform, the

CISTELA SERRICORNIS

joints serrated; body ovoid, arched above; feet long, but none of the legs formed for leaping; penultimate joint of the tarsi bifid; mandibles entire. They generally live amongst leaves and flowers. They are an important group numerically, both as regards genera and species, several being found in this country.

CITILLUS. A small Rodent animal, of the genus *Spermophilus*, with a long thin body, short tail, and of a silvery grey colour. It is a native of the northern parts of Europe, and dwells in communities, great numbers of them being usually found together in the same cave, furnished with a store of nuts, chestnuts, &c. Their flesh is well flavoured, and their skins are much valued. [See *Spermophilus*.]

CIVET. (*Viverra civetta*.) This animal, popularly known by the name of the Civet-cat, belongs to a genus of carnivorous, mammiferous quadrupeds, and is a native of several parts of Africa and India. It is particularly distinguished by having a secretory glandular receptacle, situated at some little distance beneath the tail, wherein is formed a powerfully odorous matter called civet. In general appearance, this animal reminds one of the fox, which it also resembles in its predatory habits; but the legs are short, the tail is long, hairy, and cylindrical, and the claws, though by no means so acute as those of the cat, are still partially retractile. The ground colour of the body is yellowish-grey, with large dusky spots

disposed in longitudinal rows on each side; and a sort of upright mane on the neck and back. The tongue is covered with stout, horny prickles; and the ears are straight and rounded at the tips. The pouch, situated near the genitals, is a deep bag, sometimes divided into two cavities, whence a thick, oily, and strongly musk-like fluid is poured out. When good, this odorous substance is of a clear yellowish or brown colour, and of about the consistence of butter; when undiluted, the smell is powerful and very offensive, but when largely diluted with oil or other ingredients, it becomes an agreeable perfume. Important medicinal virtues were formerly attributed to the civet; it, however, not only no longer forms an article in the Materia Medica, but even as a perfume it has been laid aside. The foregoing description will apply to another species, the *Viverra zibetha*, except that this has no mane: it should be observed also, that the *Viverra civetta* is peculiar to Africa, and the *zibetha* to Asia.

CLADOCERA. An order of minute Crustacea, characterized by the body being inclosed in a hivalve shell, including, among others, the genus *Daphnia*.

CLAM. The shell of a species of Conchiferous Mollusca. [See *TRIDACNA*.]

CLAUSILIA. A genus of Mollusca chiefly inhabiting mosses at the foot of trees. The species are very numerous, and they are all small shells, in shape somewhat resembling the pupa or chrysalis of an insect; the largest scarcely exceeding an inch in length. Within the mouth, in the last whorl but one, there is a little elastic shelly plate attached to the shell, and called a *clausium*, from which the genus takes its name. It is used to close up the aperture when the animal has retreated within its shell, and in that respect resembles an operculum, except that the latter is attached to the animal, or is loose and thrown off, whereas the former is fixed permanently to the shell.

CLAVIGER. A genus of Coleopterous insects, of the section *Trimera*; characterized by six-jointed antennæ, the maxillary palpi very short, and the eyes apparently wanting. The species are found under stones, and in the nests of small yellow Ants. One was found a few years ago in a nest of *Formica flava*, by Mr. J. O. Westwood, at Ensham, Oxon, and it was considered one of our rarest insects; but Mr. F. Smith says (in the Zoologist), "I have been an examiner of ants' nests, and an observer of their habits, some years, and have searched in scores of the nests of *Formica flava* for the *Claviger*; and this perhaps is the reason why I have not found it. In the immediate neighbourhood of London there are no stony fields like those in chalky districts; and where the soil is subject to retaining a greater degree of moisture, like the London clay, the ant appears to find it necessary to raise up a hillock like a mole-hill, to the upper chambers of which she conveys her larvae, eggs, and pupæ, as the atmospheric changes

render it necessary; but, on the contrary, at Mickleham I did not observe a single instance of any superstructure being raised, for, in a soil so light as in some places barely to cover the strata of chalk, the ant is glad to find a situation so suited to her purpose as the under side of a large stone, for here the necessary degree of moisture for the development of her progeny is retained in the earth. Now it will be obvious that the difficulty of detecting the *Claviger* amongst the accumulations of the ant-hill must be very great, but on removing the stones you are at once, as it were, admitted into the channels of the nest, filled with eggs, larvae, and pupæ, and amongst these it is that *Claviger* is found. The first question which naturally arises is this:—What is the nature of the connexion between the two insects? P. W. J. Müller, in *German's Magazin der Entomologie*, informs us that the ants altogether support the *Clavigers* for the sake of a peculiar secretion which exudes from them, and which the ants suck from the two folds of hair that terminate the external angles of the elytra,—that the ants occasionally caress the *Clavigers*, which then give out a fresh supply of the fluid,—that the *Claviger* is wholly dependent for support on the ants, and that they feed it with juices extracted from flowers, &c. * * * I am inclined to the opinion that the only purpose for which these insects are retained by the ants, is for the sake of the fluid which they extract from them; I feel convinced that there are hundreds of nests without them: they are most numerous during the early summer months, whilst the larvae are in the nests; and I was at one time inclined, from that circumstance, to think that the fluid extracted from them might serve to nurture

CLAVIGER LONGICORNIS.

particular sexes of ants, but the fact of their not inhabiting every nest at once decides the question." The species figured is the *Claviger longicornis*, which differs considerably from the preceding, but has the same general appearance.

CLAVICORNES. The name given to a family of Pentamerous beetles, whose antennæ end in a club-shaped enlargement: they are partly terrestrial, and partly aquatic.

CLAY [MOTHS]. A name given by collectors to Moths of the genus *Graphiphora*.

CLEAR-WING [HAWK-MOTHS]. A name given to the species of *Sphingidæ*, belonging to the genus *Egeria*.

CLERUS: CLERIDÆ. A genus and family of Coleopterous insects, of small extent; generally handsomely variegated in their colours, and seldom exceeding an inch in length: the body is firm, long, and often cylindric, with the head and thorax narrower than the elytra; and the antennæ are short, sometimes filiform and serrated. The species of the genus *Clerus* are amongst the largest of the family; having the elytra generally of a bright red colour, ornamented

HIVE BEETLE
(CLERUS [TRICHODES] APIARIUS.)

with purple spots. The perfect insects extract the honey from flowers; but their larvae, which are of a bright red colour, are very destructive to bees and wasps, in the nests of which the females deposit their eggs during the absence of those insects, upon whose grubs the larvae of the *Clerus* prey; they begin in the cell where they were hatched, and proceed from cell to cell, devouring each inhabitant until they arrive at maturity.

CLIO: CLIONIDÆ. A genus and family of naked marine molluscs, belonging to the order *Pteropoda*. They are particularly distinguished by having a pair of fin-like organs, or wings, consisting of an expansion of the mantle on each side of the neck, and furnished with muscular fibres—a peculiarity of structure by which they are enabled to propel themselves rapidly through the water.

CLIO BOREALIS

So numerous are they in the Northern and Southern oceans, that the water appears literally alive with them; they are called whales' food, and the sea is sometimes so glutted with the *Clios*, that the whales can scarcely open their mouths without ingulphing thousands of them. The *Clio borealis* of the North and the *C. australis* of the South

are equally abundant in the regions to which they belong.

CLIONA. A kind of Sponge. [See *SURREL*.]

CLOTHO. A genus of spiders, which inhabit Egypt and the south of Europe, remarkable for the curious nest or habitation which it constructs for its young. This is indeed a singular genus. The best known species (*Clotho Durandii*) is about half an inch long, of a brown maroon colour, with the abdomen black, marked with five yellowish spots. It constructs on the under side of stones, or in crevices of rocks, a cocoon in the shape of a cap or patella, an inch in diameter, its circumference having seven or eight festoons; the points alone being fixed to the stone by means of threads, whilst the edges of the festoons are free. This singular tent, the outer surface resembling the finest taffety, is composed of a number of folds. When young it only constructs two layers, between which it takes its station. But subsequently, perhaps at each moulting, it adds other folds, and when the period of reproduction arrives it weaves another apartment expressly for the reception of the sacs of eggs, and young when hatched, of a softer texture. The inside of its habitation is always remarkably clean. The bags in which the eggs are placed are four, five, or six in number in each habitation; they are about one-third of an inch in diameter, and of a lentileular form. The eggs are not deposited till about the end of December or in January, and they are enveloped in fine down to guard them from the cold. The edges of the festoons not being fastened together, the insect is able to creep in and out at will by lifting them up. When the young are able to dispense with the maternal cares, they quit their common habitation and form separate abodes, and their parent dies in her tent, which is thus its birthplace and its tomb.

CLOUDED YELLOW [BUTTERFLY].

A name applied by insect collectors to Butterflies of the genus *Colias*.

CLUPEA: CLUPEIDÆ. A genus and family of Malacopecterygous fishes; distinguished by their wanting the adipose fin, by having the upper jaw composed of the intermaxillary bones in the middle, and the maxillaries at the sides, and by the body being always covered with scales. To this genus belong the Herring, Sprat, Shad, Whitebait, &c. [which see].

CLYTUS. A genus of Longicorn Beetles, abounding in species. A few species (*C. nrisiis* and *C. arcantus*) are found in this country; but we prefer quoting, from Dr. Harris's work, his description of two North American species, on account of the interesting notices of the habits of *CLYTUS SPECIOSUS*:—This beautiful Clytus, like the other beetles of the genus to which it belongs, is a wood-borer; and the noble sugar-maple, which is one of the most beautiful of American forest-trees, is doomed to suffer from its depredations. The Clytus is distinguished from a *Callidium* by its more convex form, its more nearly globular thorax, which is neither flattened nor in-

dented, and by its more slender thighs. The head is yellow, with the antennæ and the eyes reddish black; the thorax is black, with two transverse yellow spots on each side; the wing-covers, for about two-thirds of their length, are black, the remaining third is yellow, and they are ornamented with bands and spots arranged in the following manner: a yellow spot on each shoulder, a broad yellow curved band or arch, of which the yellow scutellum forms the key-stone, on the base of the wing-covers, behind this a zigzag yellow band forming the letter W, across the middle another yellow band arching backwards, and on the yellow tip a curved band and a black spot; the legs are yellow; and the under-side of the body is reddish yellow, variegated with brown. It is the largest known species of Clytus, being from nine to eleven tenths of an inch in length, and three or four tenths in breadth. It lays its eggs on the trunk of the maple in July and August. The grubs burrow into the bark as soon as they are hatched, and are thus protected during the winter. In the spring they penetrate deeper, and form, in the course of the summer, long and winding galleries in the wood, up and down the trunk. In order to check their devastations, they should be sought for in the spring, when they will readily be detected by the sawdust that they cast out of their burrows; and, by a judicious use of a knife and stiff wire, they may be cut out or destroyed before they have gone deeply into the wood. Many kinds of Clytus frequent flowers, for the sake of the pollen which they devour.

CLYTUS PICTUS. This other North American species has the form of the beautiful Maple Clytus. It is velvet black, and ornamented with transverse yellow bands, of which there are three on the head, four on the thorax, and six on the wing-covers, the tips of which are also edged with yellow. The first and second bands on each wing-cover are nearly straight; the third band forms a V, or, united with the opposite one, a W, as in the *C. speciosus*; the fourth is also angled, and runs upwards on the inner margin of the wing-cover towards the scutellum; the fifth is broken or interrupted by a longitudinal elevated line; and the sixth is arched, and consists of three little spots. The antennæ are dark brown; and the legs are rust-red. These insects vary from six-tenths to three quarters of an inch in length. We are informed by Dr. Harris, that in the month of September these beetles gather on the locust-trees, where they may be seen glittering in the sunbeams with their gorgeous livery of black velvet and gold, coursing up and down the trunks in pursuit of their mates, or to drive away their rivals, and stopping every now and then to salute those they meet with a rapid bowing of the shoulders, accompanied by a creaking sound, indicative of recognition or defiance. Having paired, the female, attended by her partner, creeps over the bark, searching the crevices with her antennæ, and dropping therein her snow-white eggs, in clusters of seven or eight together, and at intervals of five or six minutes, till her whole stock is safely stored. The eggs

are soon hatched; and the grubs immediately burrow into the bark, where they remain during the ensuing winter in a torpid state, but in spring they bore more or less deeply into the trunk, the general course of their winding and irregular passages being in an upward direction from the place of their entrance.

COAL-FISH. (*Gadus carbonarius*.) A Malacopterygious fish, inhabiting the Baltic, the Northern, and the Mediterranean seas; it is common on most of our rocky and deep coasts, but particularly on those of Scotland, the Orkneys, and Yorkshire. The head and body are elegantly shaped; the scales small and oblong; the lateral line silvery white and nearly straight; the under jaw is somewhat longer than the upper; the lips tinged with purple red; the mouth black; the teeth very small; and the irides silvery white. When full grown, it is about two feet and a half long, and weighs thirty pounds; the head, dorsal fins, tail, and upper parts of the body are of a dusky black, which gradually softens into a silvery tinge as it approaches the abdomen; the tail is broad and forked. According to Mr. Pennant, the young begin to appear in vast shoals on the

COAL-FISH. — (*GADUS CARBONARIUS*.)

coast of Yorkshire, in July, and are at that time about an inch and a half long; in August they are from three to five inches in length, and are taken in great numbers with the rod and line, when they are esteemed a very delicate fish, but when about a year old they are so coarse that few people will eat them. Mr. Couch says, "It is in the highest condition from October to December, at which season it prowls after prey in large companies; so that when met with they prove a valuable capture to the fishermen; for though but coarse food, yet being wholesome, substantial, and cheap, they are eagerly purchased by the poor, either fresh or salted. They swim at no depth, and with great rapidity; but when attracted by bait, will keep near a boat till all are taken; and I have known four men in two boats, two men in each boat, take twenty-four hundred weight with lines in a very few hours. The season for spawning is early in spring; immediately after which this fish becomes so lank as to be worthless, in which state it continues through the summer."

These fish derive their English name from the dusky pigment which tinges their skin, and which, when they are handled, soils the fingers like moist coal. The young resort to the rocky bays of the Orkneys and Hebrides in immense numbers, where, according to the period of their growth, they are known by the names of *cuddy*, *sithe*, and *sillock*. On the Yorkshire coast the young are called *parrs*, and when a year old *billets*.

COATIMONDI. (*Nasua*.) An animal bearing some affinity to the racoon, except that the neck and body are longer, the fur is shorter, and the eyes are smaller; but it is more particularly distinguished by the elongation of its snout, to which its scientific name *nasua* refers. By the assist-

RUFUS COATIMONDI — (*NASUA RUF.*)

ance of this long flexible snout, which is somewhat truncated at the end, it roots up the earth, in the manner of a hog, in quest of earth-worms, &c. It also preys on the smaller quadrupeds; but it lives more upon trees than upon the ground, and is a destructive enemy of birds, their eggs, and unfledged young. It is equal in size to a large cat; its general colour is a cinereous brown; the tail, which is of very considerable length, is annulated with distinct circles of black; the ears are round, like those of a rat, covered with short hair externally, but internally with long whitish hair; the mouth is large, and the under jaw much shorter than the upper. It is a native of Brazil.

COBITIS. [See LOACH.]

COBRA DI CAPELLO. The Portuguese name of the *Pipera naja*; called by the English names of the Hooded Snake and the SPECTACLE SNAKE. [See SNAKE.]

COCCINELLA: COCCINELLIDÆ. A genus and family of Coleopterous insects, characterized by their hemispheric form, the upper part being convex, and the lower flat; and further distinguished by the colour and spots of their wings. Among these are included all the Lady-birds; one of which is the *Coccinella septempunctata* of Linnaeus, or common seven-spotted Lady-bird, the well-known summer visitant of every field and garden. Though these insects sometimes appear in great numbers, and have occasionally created much alarm, it is erroneous to suppose that they do any injury to vegetation; on the contrary, both in the larva and perfect state, they feed on the *Aphides* which infest plants, and are consequently of

great service: its larva has a rather disagreeable appearance; it is of a long oval shape, with a pointed tail, of a black colour,

LADY-BIRD, WITH ITS LARVA AND PUPA.
(*COCCINELLA SEPTEMPUNCTATA*.)

with red and white specks, and a rough surface; it changes to a short, blackish, oval chrysalis, spotted with red, and which gives birth to its beautiful immate in the months of May and June.

The different species of *Coccinellæ* are very numerous; they are generally divided according to the ground-colour of their elytra, which are either red with black, yellow with black, black with red, or yellow with white spots. One of the most beautiful of the English species is the *Coccinella octodecimpunctata* of Linnæus, or the eighteen-spotted Lady-bird, which is of a bright yellow with numerous black specks, and little more than half the size of the common red kind above described.

Most people who are familiar with our South-eastern coasts have had opportunities of witnessing the sight of extraordinary swarms of Lady-birds during the summer or autumnal months. The most recent instance of this which we have seen publicly noticed is the following:—"On Friday, August 13, 1847, the whole of the coast around Southend was visited by one of the most numerous flights of insects on record. They consisted of at least five species of lady-bird, and they came in such dense numbers, as for miles along the coast to resemble a swarm of bees during living. The sea destroyed countless millions of them, the grass and hedge-rows, and every crevice that afforded shelter from the wind, were coloured with their numbers, and for many miles it was impossible to walk, without crushing numbers beneath the tread. The insects evidently came from the east, the wind having veered round to that point during the night. Every true friend of agriculture, however, hails the appearance of these insects, as they are well-known to be the destroyers of *Aphides*, a race of flies the most injurious to vegetation. We found, on inquiry, that this phenomenon was not confined to the above mentioned locality; for on the same day Ramsgate, Margate, Brighton, and the coasts of the adjacent neighbourhoods were similarly visited by swarms of these Aphidivorous insects, which in many places were swept off the public walks, and speedily consigned to a watery tomb."

Dr. Thaddeus Harris has the following

sensible remarks on the valuable services of the *Coccinellæ*, when speaking of the "redoubtable enemies" which "seem expressly created to diminish the numbers" of the *Aphides*, or plant-lice. "These lice-destroyers are of three sorts. The first are the young or larvæ of the hemispherical beetles familiarly known by the name of lady-birds, and scientifically by that of *Coccinellæ*. These little beetles are generally yellow or red, with black spots, or black, with white, red, or yellow spots; there are many kinds of them, and they are very common and plentiful insects, and are generally diffused among plants. They live both in the perfect and young state, upon plant-lice, and hence their services are very considerable. Their young are small flattened grubs of a bluish or blue-back colour, spotted usually with red or yellow, and furnished with six legs near the fore-part of the body. They are hatched from little yellow eggs, laid in clusters among the plant-lice, so that they find themselves at once within reach of their prey, which, from their superior strength, they are enabled to seize and slaughter in great numbers. There are some of these lady-birds of a very small size, and blackish colour, sparingly clothed with short hairs, and sometimes with a yellow spot at the end of the wing-covers, whose young are clothed with short tufts or flakes of the most delicate white down. These insects belong to the genus *Scymnus*, which means a lion's whelp, and they well merit such a name, for their young, in proportion to their size, are as sanguinary and ferocious as the most savage beast of prey. I have often seen one of these little tufted animals preying upon the plant-lice, catching and devouring, with the greatest ease, lice nearly as large as its own body, one after another, in rapid succession, without apparently satiating its hunger or diminishing its activity." M. Mulsant, of Lyons, has published a volume on the *Coccinellidæ* of France, most of which are also found in this country: a monograph of the whole group by the same learned entomologist is in the press.

COCCUS. A genus of Hemipterous insects, including the Cochineal insect (*Coccus cacti*.) In this remarkable genus the males are much smaller than the females, and are furnished with wings, of which the females are destitute. The Coci are found on the leaves and bark of various plants: hence they become injurious to many exotics in our hothouses and conservatories. One of the most common of these is the *Coccus adonidum*, a small oval-shaped insect of a pale rose-colour, slightly convex above, with the body divided into many transverse segments projecting sharply on the sides: it has six short legs, and the whole insect appears more or less covered with a fine white powder. When the female is full of eggs, she ceases to feed, and remaining fixed to one spot, envelops herself in a fine white fibrous cotton-like substance, and soon afterwards dies: the young, which are hatched under the body of the parent insect, proceeding from it in great numbers, and dis-

persing themselves in quest of food. It was originally introduced into Europe along with exotic plants from the warmer regions of Africa and America.

It may be remarked of the *Coccidæ* generally, that they are remarkable for their powers of propagation, and that when they once attack a plant or young tree, the minute size of the larvæ renders their extermination a very difficult task. We were particularly struck with the observations of the President of the Entomological Society (G. Newport, Esq. F. R. S.) in his "Anniversary Address," 1845—that so complete had been the ravages of the Coccus of the orange-trees, that one of the Azores, the island of Fayal, lost its entire produce from this cause alone. The usual exportation of fruit from Fayal had been 12,000 chests annually, but in 1843 not a single chest was exported. This injury had extended to St. Michael's; and the inhabitants of the whole of that group of volcanic islands, depending almost entirely on the produce of their orange-groves, and despairing of retrieving their prospects, were fast turning their attention to the cultivation of other objects of commerce. This amount of injury to a whole population, by a diminutive and apparently contemptible insect, was the result of but three years! It was therefore with great reason that the President laid some stress on the fact, and remarked, that the effects of this insect on a single article of luxury might fairly be adduced to show that entomological inquiries are deserving of full attention. They furnish, however, some very important products: the bodies of many species, being deeply coloured through their whole substance, yield dyes of great value, the richness of which seems to depend upon the nature of the plant upon which they feed.

By far the most important of all is the *Coccus cacti*, or COCHINEAL CACTUS, so celebrated for the beauty of the colour which it yields. This species is a native of South America, and was for a long time exclusively confined to Mexico, where it feeds on a species of cactus. The female or officinal Cochineal insect, in its full-grown pregnant or torpid state, swells or grows to such a size, in proportion to that of its first or creeping state, that the legs, antennæ, and proboscis, are so small with respect to the rest of the animal as hardly to be discovered by the naked eye; so that on a general view it bears a great resemblance to a seed or berry: hence arose that difference of opinion which at one period subsisted among writers; some maintaining that Cochineal was a berry, while others contended that it was an insect.

When the female insect is arrived at its full size, it fixes itself to the surface of the leaf, and envelopes itself in a kind of white down, which it spins or draws through its proboscis in a continued double filament. The male is a small and rather slender two-winged fly, about the size of a flea, with jointed antennæ and large white wings in proportion to the body, which is of a red colour, with two long filaments proceeding from the tail. When the female insect has discharged all its eggs, it becomes a mere

husk, and dies; so that great care is taken to kill the insects before that time, to prevent the young from escaping. The operation of

COCHINEAL INSECT - (COCCUS CACTI.)

collecting the insects, which is exceedingly tedious, is performed by the women. "Formerly," says Mr. McCulloch, "it was in Mexico only that it was reared with care, and formed a valuable article of commerce; but its culture is now more or less attended to in various parts of the West Indies and of the United States. There are two sorts or varieties of Cochineal: the best or domesticated, which the Spaniards call *grana fina*, or fine grain; and the wild, which they call *grana sylvestra*. The former is nearly twice as large as the latter; probably because its size has been improved by the favourable effects of human care, and of a more copious and suitable nourishment, derived solely from the *Cactus cochineifer*, during many generations. Wild cochineal is collected six times in the year; but that which is cultivated is only collected thrice during the same period. The insects, of which there are about 70,000 in a pound, being detached from the plants on which they feed by a blunt knife, are put into bags, and dipped in boiling water to kill them, after which they are dried in the sun. It is principally used in the dyeing of scarlet, crimson, and other esteemed colours. The watery infusion is of a violet crimson; the alcoholic, of a deep crimson; and the alkaline, of a deep purple, or rather violet hue. It is imported in bags, each containing about 200 lbs.; and has the appearance of small, dry, shrivelled, rugose berries or seeds, of a deep brown, purple, or mulberry colour, with a white matter between the wrinkles."

COCK. (*Gallus domesticus*.) The common domestic Cock, the well-known chieftain of the poultry-yard, is subject to innumerable varieties, scarcely two being found to resemble each other exactly in form and plumage. At what time this valuable bird was brought under the control of man, it is now impossible to determine; but, as the forests of many parts of India still abound

with several varieties of the Cock in the wild or natural condition, it is quite reasonable to conclude that the race was first domesticated in the East, and gradually extended thence to the rest of the world. It seems to be generally understood, indeed, that the Cock was first introduced into Europe from Persia: it has, however, been so long established throughout the Western regions, that to attempt to trace its progress from its native wilds would be a useless waste of time. We figure what many naturalists regard as the origin of our domestic poultry, the very handsome Javanese wild fowl; but it is our firm belief that domesticated animals are in general not traceable to any wild stock or race.

THE JAVANESE COCK.—(*GALLUS BANKIVUS*.)

The Domestic Cock has his head surmounted by a notched, crimson, fleshy substance, called a *comb*; and two pendulous fleshy bodies of the same colour, termed *wattles*, hang under his throat. The hen has also a similar, but not so large nor so vividly coloured excrescence on her head. The Cock is provided with a sharp horn or spur on the outside of his tarsus, with which he inflicts severe wounds; the hen, instead of a spur, has a mere knot or tubercle. There is, in both sexes, below the ear, an oblong spot, the interior edge of which is reddish, and the remainder white. The feathers arise in pairs from each sheath, touching by their points within the skin, but diverging in their course outwards. On the neck they are long, narrow, and floating; on the rump they are of the same form, but drooping laterally over the extremity of the wings, which are quite short, and terminate at the origin of the tail, the plumes of which are vertical. In the centre of the Cock's tail are two long feathers, which fall backwards in a graceful arch, and add great beauty to the whole aspect of the fowl. It is in vain to offer any description of the colour of the plumage, as it is infinitely varied, being in some breeds of the greatest richness and elegance, and in others of the simplest and plainest hue. Except in the pure white breeds, the plumage of the cock is always more splendid than that of the hen: his apparent consciousness of personal beauty, courage, and gallantry, seem never to forsake him, whether we regard his stately march,

at the head of his train of wives and numerous offspring, or watch him as he crows defiance to a rival. His sexual powers are matured when he is about six months old, and his full vigour lasts for about three years.

The hen, if left to herself, forms a very indifferent nest: a simple hole scratched in the ground among a few bushes is the only preparation she usually makes, and she generally lays from twelve to fifteen eggs before she begins to sit upon them for the purpose of hatching. But she now becomes a model of enduring patience, remaining fixed in her place until the urgency of hunger forces her to go in search of food. During the time of her sitting she diligently turns and shifts her eggs, so that each may receive a due degree of genial warmth; and it is not until about three weeks have elapsed that the incubation is completed. The strongest of the progeny then begin to chip the shell with the bill, and are successively enabled to burst their brittle prisons. The whole family being at length emancipated, the parent leads them forth in search of food. In her nature the hen is timid; but in discharging the duties of maternity she becomes bold, and indiscriminately attacks every aggressor, watches over the safety of her young with the utmost jealousy, neglects the demands of her own appetite to divide the food she may obtain among her nurslings, and labours with untiring diligence to provide them with sufficient sustenance.

The Cock is very attentive to his females, hardly ever losing sight of them; he leads, defends, and cherishes them; collects them together when they straggle, and seems to eat unwillingly till he sees them feeding around him. Mons. Parmentier, a celebrated French naturalist, has thus described the Cock:—"He is considered to have every requisite quality when he is of a good middling size; when he carries his head high; has a quick animated look; a strong and shrill voice, short bill, and fine red comb, shining as if varnished; wattles of a large size, and of the same colour as the comb; the breast broad; the wings strong; the plumage black, or of an obscure red; the thighs very muscular; the legs thick, and furnished with strong spurs; the claws rather bent, and sharply pointed. He ought also to be free in his motions, to crow frequently, and to scratch the ground often in search of worms, not so much for himself as to treat his hens. He ought vithal to be brisk, spirited, ardent, and ready in caressing the hens; quick in defending them, attentive in soliciting them to eat, in keeping them together, and in assembling them at night."

After the common or dunghill breed which we have described, the principal varieties are—The *GAME COCK*, which is more distinguished for its unusual length of spur, and its courage, than for any great peculiarity in its plumage; the *DORKING* fowl, which has two toes behind, and is considerably larger than the other European species; the *POLAND* breed, which is black-feathered, with white topknots; the *BANTAM COCK*,

a small but most courageous fowl, whose legs are so much feathered as to hinder it greatly in walking; and the DWARF COCK, much smaller than the Bantam, with legs so short that the wings drag on the ground.

COCKCHAFER, or MAY-BUG. (*Melolontha vulgaris*.) This is one of the most common of European beetles, and in this country there is no one with which we are more familiar, the larvæ or caterpillar feeding on the roots of corn, &c., and the complete insect making its appearance during the middle and the decline of summer. It is found on most of the deciduous trees; particularly the oak and willow, and on the hazel and other fruit trees; and often in such numbers that branches bend under their weight. Its duration in the perfect state is very short, each individual living only about a week, and the species entirely disappearing in the course of a month. After the sexes have paired, the males

COCKCHAFER AND ITS LARVA
(*MELOLONTA VULGARIS*.)

perish, and the females enter the earth to the depth of six inches or more, making their way by means of the strong hook which arm the fore-legs; here they deposit their eggs, amounting from one to two hundred from each female, which are abandoned by the parent, who generally ascends again to the surface, and perishes in a short time.

From the eggs are hatched, in the space of fourteen days, little whitish grubs, each provided with six legs near the head, and a mouth furnished with strong jaws. When in a state of rest, these grubs usually curl themselves in the shape of a crescent. They subsist on the tender roots of various plants, committing ravages among these vegetable substances, on some occasions of the most deplorable kind, so as totally to disappoint the best-founded hopes of the husbandman. During the summer they live under the thin coat of vegetable mould near the surface, but as winter approaches they descend below the reach of frost, and remain torpid until the succeeding spring, at which time they change their skins, and re-ascend to the surface for food. At the end of their third summer they have acquired their full growth as larvæ; they then cease eating, and void the residue of their food, preparatory to the metamorphosis which they are about to undergo. As this period approaches they bury themselves deeper in the earth, where they form a rounded cavity, the sides of which are smoothed and consolidated by

the application of a fluid disgorged from their mouths. Its abode being thus formed, the larva soon begins to contract in length, swell, and burst its last skin, coming therefrom in the form of a chrysalis, exhibiting the rudiments of elytra, antennæ, &c., and gradually acquiring consistence and colour till it becomes of a brownish hue. In this state it continues about three months, by the end of which time it assumes its rank as a perfect coleopterous insect. During the months of March and April the insect approaches the surface of the earth, and generally bursts from its subterraneous abode during some mild evening about the latter end of May, thus quitting its grovelling mode of life, to soar aloft and disport in the realms of air.

In their winged state, these beetles, with several other species, act as conspicuous a part in injuring the trees, as the grubs do in destroying the herbage. During the month of May they come forth from the ground, whence they have received the name of May-bugs or May-beetles. They pass the greater part of the day upon trees, clinging to the under sides of the leaves, in a state of repose; but as soon as evening approaches, they begin to buzz about among the branches, and continue on the wing till near midnight. In their droning flight they move very irregularly, darting hither and thither with an uncertain aim, hitting against objects in their way with a force that often causes them to fall to the ground. They frequently enter houses in the night, apparently attracted, as well as dazzled and bewildered, by the lights. Their vagaries, in which, without having the power to harm, they seem to threaten an attack, have caused them to be called *dors*, that is, *drasers*; while their seeming blindness and stupidity have become proverbial, in the expressions, "blind as a beetle," and "beetle-headed." Besides the leaves of fruit-trees, they devour those of various forest-trees and shrubs, with an avidity not much less than that of the locust; so that, in certain seasons, and in particular districts, they become an oppressive scourge, and the source of much misery to the inhabitants.

The animals and birds appointed to check the ravages of these insects, are, according to Latreille, the badger, weasel, marten, bats, rats, the common dung-hill fowl, and the goat-sucker or night-hawk. To this list may be added the common crow, which devours not only the perfect insects, but their larvæ, for which purpose it is often observed to follow the plough. In "Anderson's Recreations," it is stated that "a cautious observer, having found a nest of five young jays, remarked that each of these birds, while yet very young, consumed at least fifteen of these full-sized grubs in one day, and of course would require many more of a smaller size. Say, that on an average of sizes, they consumed twenty a-piece, these for the five make one hundred. Each of the parents consumes say fifty; so that the pair and family devour two hundred every day. This, in three months, amounts to twenty thousand in one season. But as the grub continues

in that state four seasons, this single pair, with their family alone, without reckoning their descendants after the first year, would destroy eighty thousand grubs. Let us suppose that the half, namely, forty thousand, are females, and it is known that they usually lay about two hundred eggs each; it will appear that no less than eight millions have been destroyed, or prevented from being hatched, by the labours of a single family of jays. It is by reasoning in this way, that we learn to know of what importance it is to attend to the economy of nature, and to be cautious how we debase it by our short-sighted and futile operations.

From Vincent Kollar's useful work on the injuries done to vegetation by various insects, (translated from the German by the Misses London) we derive the following information. "The May-bug is able to do mischief in a double form;—viz. as larva and beetle, in seasons when its increase exceeds the proper limits. The larvæ spare neither meadow nor corn-fields; they often destroy potatoes and other vegetables, and even gnaw the roots of trees and vines, so as to make them sickly. They do particular injury in nurseries, where seeds are raised, to the young plants. By attentively observing the appearance of the young trees, the presence of the larvæ of the May-bug gnawing at the roots may be detected. The plants thus deprived of their roots become yellow and parched, and are easily taken out of the ground. Young fir-trees are not less exposed to the attacks of this insect than deciduous trees. These insects must not be looked for under the already parched-up trees, but under those that are withering; as the former are already deserted from want of nourishment. The fully formed beetle is still more destructive than the larvæ. It attacks cherry, apple, pear, and nut trees, the vine, the oak, and the beech, &c. in multitudes. The leaves and fruit of the trees, when this is the case, are completely destroyed; and the stems, full of sap, become unhealthy, and either recover slowly, or die off. It is worthy of remark, that these insects spare the lime-tree. It is natural that the agriculturist, gardener, and forester should try to discover a method by which so powerful an enemy in their peculiar province may be lessened in number or destroyed. It is impossible to search for the small eggs in the earth; and to dig up the grubs that lie deep in the ground would be attended with an expense which would far exceed that of the ravages they commit, while collecting those which are thrown up by the plough and the spade is not to be taken into consideration. Nothing remains to be done but to catch the fully-formed beetle. Nature, however, as in all other extreme visitations, has provided a more effectual remedy for this evil than can be devised by man. Birds, moles, field-mice, a multitude of birds (particularly the crow, raven, jackdaw, the woodpecker, and the hawk), and even the large ground-beetles, (*Carrabidae*) instinctively search out the May-bug and its larvæ to feed on. Unfavourable weather often comes on, and if the month of May is wet and cold, the success of the

May-bug is at an end; but in order to aid in lessening their too great increase, country magistrates and managers of forests should issue a strict order every spring to the farmers, gardeners, and labourers, to search for and collect these insects as soon as they appear in the gardens, hedges, and forests. For this purpose the children of the peasantry in the country, and those of the lower classes in towns, should be employed and encouraged by rewards. This business should take place in the morning, because the May-bugs, which have been sitting on the blossoms of the trees during the night have become as if torpid, and as long as the branches remain still they do not cling tightly to them with their hooks; in this state they can easily be thrown down in heaps. In shaking the trees, care should be taken that there are no nails or iron on the soles or heels of the shoes of the boys who climb up the branches, so that the abundant sap and tender bark of the trees may not be injured. In order to facilitate the collecting of the fallen beetles, a linen cloth should be spread under each tree, otherwise they will crawl away in the grass. This practice should be continued throughout May, and even to the beginning of June. The collected insects may be killed by pouring boiling water over them, and given as food to fowls and swine; or they may be burnt. It is not advisable either to bury them or to throw them into ponds or rivers, because they would make their way out again, and commit new ravages. Nurseries are best protected by leaves being strewn over the surface of the ground, because (as it is asserted) the beetle never lays its eggs in ground covered with litter.

"Another method of setting a limit to the too great increase of the Cockchafer consists in sparing those birds before named which feed on them, and amongst them the crow undoubtedly claims the first place. These birds follow the plough for the express purpose of consuming worms, the larvæ of insects, and particularly those of the Cockchafer, which are thrown on the surface by the plough. The instinct of the crow to go in quest of this grub, may also be observed in gardens and other places where vegetables are planted. It walks about between the plants, and soon as it sees one that has begun to wither, it approaches it with a joyful spring, digs with its sharp bill deep into the ground near the plant, and knows so well how to seize its prey, that it draws it forth and swallows it almost in the same moment. The crows do the same in meadows, which we sometimes see completely covered with them."

COCKATOO. The Cockatoos belong to the *Psittacidae*, or Parrot family, but are distinguished from the true parrots, and all others, by a crest, or tuft of elegant feathers, on the head, which they can raise or depress at pleasure. They are in general natives of Australia and the Indian Islands, inhabiting the woods, and feeding upon seeds and fruits. They make their nests in decayed trees, and if taken at an early age are easily tamed.

Before we proceed to describe some of the species, we beg to copy from the pages of Capt. Grey (*Travels in Australia*) a most interesting description of "Cockatoo killing." "Perhaps as fine a sight as can be seen in the whole circle of native sports is the killing Cockatoos with the kiley, or boomerang. A native perceives a large flight of Cockatoos in a forest which encircles a lagoon; the expanse of water affords an open clear space above it, unencumbered with trees, but which raise their gigantic forms all around, more vigorous in their growth from the damp soil in which they flourish: and in their leafy summits sit a countless number of Cockatoos, screaming and flying from tree to tree, as they make their arrangements for a night's sound sleep. The native throws aside his cloak, so that he may not even have this slight covering to impede his motions, draws his kiley from his belt, and, with a noiseless, elastic step, approaches the lagoon, creeping from tree to tree, from bush to bush, and disturbing the birds as little as possible; their sentinels, however, take the alarm, the Cockatoos farthest from the water fly to the trees near its edge, and thus they keep concentrating their forces as the native advances; they are aware that danger is at hand, but are ignorant of its nature. At length the pursuer almost reaches the edge of the water, and the scared Cockatoos, with wild cries, spring into the air; at the same instant the native raises his right hand high over his shoulder, and, bounding forward with his utmost speed for a few paces, to give impetus to his blow, the kiley quits his hand as if it would strike the water, but when it has almost touched the unruffled surface of the lake, it spins upwards with inconceivable velocity, and with the straightest conceptions. In vain the terrified Cockatoos strive to avoid it: it sweeps wildly and uncertainly through the air, and so eccentric are its motions, that it requires but a slight stretch of the imagination to fancy it endowed with life, and with fell swoops is in rapid pursuit of the devoted birds,—some of whom are almost certain to be brought screaming to the earth. But the wily savage has not yet done with them. He avails himself of the extraordinary attachment which these birds have for one another, and fastening a wounded one to a tree, so that its cries may induce its companions to return, he watches his opportunity by throwing his kiley or spear to add another bird or two to the booty he has already obtained." The preceding animated description refers not only to the species beneath, but also to species of the genus *Calyptrorhynchus*, previously described.

BROAD-CRESTED COCKATOO. (*Psittacus cristatus*.) This elegant species is about the size of a common owl; the colour white, with a faint tinge of rose-colour on the head and breast, and of yellow on the inner wing-coverts and tail-feathers; on the head is a very ample crest, consisting of large and long feathers arching over the whole head, which the bird can readily raise or depress:

these feathers are white above, but of a fine scarlet hue beneath: the tail is short in proportion to the size of the body, and even at the end; the bill very large, strong, and of a bluish black; the orbits of the eyes bare, and of a deep ash-colour, and the legs deep cinereous. It is of a mild and docile disposition, but can rarely be taught to articulate any other word than its own name, which it pronounces with great distinctness. New Holland is its locality.

GREAT SULPHUR-CRESTED COCKATOO. (*Psittacus pateritus*.) This is somewhat larger than the preceding, and measures upwards of two feet in length: its colour is white, slightly tinged with yellow on the sides of the tail, and about the wing-coverts; the head is ornamented with a large, long, and pointed crest, of a fine sulphur colour, slightly reversed at the tip; the bill is black; and the tail longer than in the Broad-crested Cockatoo. Same locality.

SMALLER SULPHUR-CRESTED COCKATOO. (*Psittacus sulphureus*.) In almost every respect except in size (being only about fifteen inches long), the description just given would apply to this species. The crest is shaped as in the preceding bird, and is of a fine sulphur-yellow; but it has in addition a large yellow spot beneath each eye. The bill is black; and the legs deep lead-colour. It is a native of the Molucca islands.

RED-VENTED COCKATOO. (*Psittacus Philippinarum*.) This is not only the smallest of the White Cockatoos, but its crest is smaller in proportion than the rest of the tribe. The bill is of a pale flesh-colour, and the legs cinereous. It is a native of the Philippine Isles.

COCKLE. [See CARDIUM.]

COCK OF THE WOODS. [See GROUSE.]

COCKROACH. [See BLATTA ORIENTALIS.]

COD. [For the generic character of the *Gadidae*, or Codfish tribe, see GADIDS.]—The **COMMON COD.** (*Gadus callarus*.) It is almost impossible to estimate too highly the importance of this truly valuable inhabitant of the deep, whether regarded as a supply of

COD — (GADUS CALLARUS.)

food, a source of national industry and commercial wealth, or as a wonder of nature in its astonishing fecundity. It resides in immense shoals in the Northern seas, performing various migrations at stated seasons, and visiting in succession the different coasts of Europe and America. Though found in considerable numbers on the coasts of other northern regions, an extent of about 450

miles of ocean, leaving the chill and rugged shores of Newfoundland, is the favourite annual resort of countless multitudes of Cod, which visit the submarine mountains known as the *Grand Bank*, to feed upon the crustaceous and molluscos animals abundant in such situations. Hither, also, fleets of fishermen regularly adventure, sure of winning a rich freight in return for their toils and exposure. "In this country," Mr. Yarrell observes, "it appears to be taken all round the coast: among the islands to the north and west of Scotland it is abundant: most extensive fisheries are carried on; and it may be traced as occurring also on the shore of almost every county in Ireland. In the United Kingdom alone, this fish, in the catching, the curing, the partial consumption and sale, supplies employment, food, and profit to thousands of the human race."

The Cod is of a moderately long shape, with the abdomen very thick and prominent; the head is large, as also are the eyes; the jaws of equal length, the lower one bearded at the tip by a single cirrus; in the jaws and palate are numerous sharp teeth; the dorsal and anal fins are rather large, the pectoral and ventral rather small; the tail of moderate size, and even at the end; the belly tumid and soft, the body tapering gradually throughout the latter half; the upper part of the head, cheeks, back, and sides, mottled and spotted with dull yellow; the belly white or silvery; the lateral line white; all the fins dusky. The Cod sometimes grows to a very large size. Pennant gives an instance of one taken on the British coasts which weighed seventy-eight pounds, and measured five feet eight inches in length, and five feet in girth round the shoulders; but the general size, at least in the British seas, is far less, and the weight from about fourteen to forty pounds; and such as are of middling size are most esteemed for the table.

Speaking of the localities to which the Cod-fish chiefly resort on our own coasts, Mr. Yarrell says, "A change has lately taken place, from the Cod having shifted their ground. Formerly the Gravesend and Barking fishermen obtained few Cod nearer than the Orkneys or the Dogger Bank: but for the last two or three years the supply for the London market has been obtained by going no farther than the Lincolnshire and Norfolk coasts, and even between that and London, where previously very few fish could be obtained." "There appear to be two well-marked varieties of the Common Cod; one with a sharp nose, elongated before the eye, and the body of a very dark brown colour, which is usually called the Dogger-bank Cod. This variety prevails also along our southern coast. The other variety has a round blunt nose, short and wide before the eyes, and the body of light yellowish ash-green colour, and is frequently called the Scotch Cod. Both sorts have the lateral line white. I believe the distinction of more southern and northern Cod to be tenable, and that the blunt-headed lighter-colour fish does not range so far south as the

sharper-nosed dark fish. Our fishermen now finding plenty of Cod-fish near home, the London shops for the last year or two have only now and then exhibited specimens of the short-nosed northern Cod: both varieties are equally good in quality, and both are frequently taken on the same ground."

COENURUS. [See SUPPLEMENT.]

COLEOPTERA. [BEETLES.] An order of Insects, having four wings, the external pair of which are not suited for flight, but form a covering or case for the interior pair, and are composed of a hard, tough substance: the inner margins of these wing-cases, or elytra, when closed, touch and form a longitudinal suture; and the inner or true wings, which are large and membranous, when not in use, are folded transversely under them. Under the term Coleoptera, therefore, are included all the beetle tribe; of which naturalists have established a great number of genera, from the different conformations of their antennae, &c.; presenting among them many that are remarkable for their brilliant colours or singular forms. The larvæ of coleopterous insects undergo a complete transformation: those which burrow in the ground generally prepare for the pupæ state by removing the earth which surrounds them so as to form an open oval space; others form a kind of cocoon or web around them; and some assume the perfect state without any preparation.

"Many of these insects, particularly in the larvæ state, are very injurious to vegetation. The Tiger-beetles (*Cicindelidæ*), the predaceous ground beetles (*Carabidæ*), the diving beetles (*Dytiscidæ*), the Lady-birds (*Coccinellidæ*), and some others, are eminently serviceable by preying upon caterpillars, plant-lice, and other noxious or destructive insects. The water-lovers (*Hydrophilidæ*), rove-beetles (*Staphylinidæ*), earwig-beetles (*Silphidæ*), skin-beetles (*Dermestidæ*), *Eurythidæ*, and *Tropididæ*, house-beetles (some of the *Nitidulidæ* and *Cleridæ*), and various kinds of dung-beetles (*Sphæridiæ*, *Histeridæ*, *Geotrupidæ*, *Copridæ*, and *Aphodiidæ*), and the *Pimeliidæ* and *Blattidæ* act the useful part of scavengers, by removing carion, dung, and other filth, upon which alone they and their larvæ subsist. Many Coleoptera (some *Staphylinidæ* and *Nitidulidæ*, *Diaperididæ*, some *Serropalpidae*, *Mycetophagidæ*, *Kryptidæ*, and *Endomychidæ*) live altogether on agarics, mushrooms, and toad-stools, plants of very little use to man, many of them poisonous, and in a state of decay often offensive; these fungus-eaters are therefore to be reckoned among our friends. There are others, such as the stag-beetles (*Lucanidæ*), some spruce-beetles (*Elateridæ*), darkling beetles (*Tenebrionidæ*), and many bark-beetles (*Heterodermidæ*, *Serropalpidae*, *Edomeridæ*, *Cucujidæ*, and some *Trogositidæ*), which, living under the bark and in the trunks and roots of old trees, though they may occasionally prove injurious, must, on the whole, be considered as serviceable, by contributing to destroy, and reduce to dust, plants that have passed their prime, and are fast going to

decay. And, lastly, the blistering-beetles (*Cantharidae*) have, for a long time, been employed with great benefit in the healing art."

COLIAS. A genus of diurnal Lepidoptera, abounding in species. See Doubleday and Hewitson's *Genera of Diurnal Lepidoptera*. We here restrict ourselves to the mention of two British species.

COLIAS HYALE, or CLOUDED YELLOW BUTTERFLY. This is a comparatively scarce British butterfly, found chiefly near the sea coast in the counties of Kent, Sussex, and Suffolk. The male is usually of a rich sulphur-yellow, the female nearly white; with a deep black spot in the middle

CLOUDED YELLOW BUTTERFLY
(*COLIAS HYALE*)

of the anterior wings, and a pale orange spot in the disc of the posterior. The anterior wings have a black border, widest towards the costa, and with a row of yellowish or whitish spots. The under wings have a large orange spot in the centre; beneath, the upper wings are whitish yellow, tipped with orange; having a black ring-spot enclosing a yellow centre near the middle, and with a row of small dusky marks at some distance from the outer margin. The lower wings beneath are entirely orange-yellow, with a row of dusky reddish spots towards the margin, and two silvery spots in the centre. The wings are all ciliated with yellowish red; the body is yellow; the head and the front of the thorax and the legs are ferruginous; the back dusky; the antennae reddish. The caterpillar is velvety-green, with two yellowish lateral lines, and black spots on the annuli: it feeds on papilionaceous plants. The chrysalis is green, with a yellow lateral line.

COLIAS EDUSA, or CLOUDED SAF-FRON BUTTERFLY. The anterior wings of the male insect are of a deep bright fulvous orange above, with a broad black internally-waved band on their outer edge, and a large round central deep black spot; the posterior wings are fulvous above, with a narrow black border on the outer edge, and a greenish tinge on the other; beneath they are greenish, with a sub-ocellated silver spot in the middle, accompanied by a smaller one. The female differs in having a series of irregular yellow spots in the black margin of the anterior wings; but each sex has a row of spots parallel with the edge of the hinder margins of both wings, of which three or four on the anterior ones are deep black, and the rest of a rust-colour: the cilia are yellow and red-brown above, and rose-coloured beneath. The body is yellowish-

green, with the back dusky: the antennae reddish; and the tip of the club inclining to yellow. In some specimens the marginal band is jet black; and the posterior wings are sometimes beautifully iridescent. It is not uncommon during the autumn in the southern counties of England, particularly on the coasts of Kent and Sussex. The caterpillar is deep green with a longitudinal white stripe on each side, spotted with blue and yellow; it feeds on grasses: the chrysalis is green, with a yellow line on each side, and black spots on the wing-cases.

COLIBRI. [See HUMMING-BIRD.]

COLIN. A South American Rasorial bird, by some writers called the Quail, but belonging to the genus *TURNIX* [which see]. There are several distinct species, all much esteemed for the delicacy of their flesh.

COLOBUS. A genus of quadrumanous animals, of which there are several species. They are natives of Africa, and are in general distinguished by their long, soft, silky hair, which covers the head and upper part of the body. Their "hands" want the thumb; hence their name, derived from the Greek word for *imperfect*. All the species of this genus, most of which are from Western Africa, are in the British Museum. A magnificent species was found by Dr. Ruppell in Abyssinia; it is black, and has long flowing white hair over the sides and back. (*C. Guereza*.) [See MONKEYS.]

COLOSSOCHELYS. (*C. Atlas*.) The name applied by Dr. Falconer and Major Cautley to a gigantic fossil Tortoise discovered by them in India, the remains of which are now in the British Museum.

The first fossil remains of this colossal Tortoise were discovered by the gentleman above-mentioned in 1835, in the tertiary strata of the Sewalik Hills, or Sub-Himalayas skirting the southern foot of the great Himalayan chain. They were found associated with the remains of four extinct species of Mastodon and Elephant, species of Rhinoceros, Hippopotamus, Horse, Anoplotherium, Camel, Giraffe, Sivatherium, and a vast number of other Mammalia, &c. The remains of many of the animals associated with the *Colossochelys* in the Sewalik Hills have been discovered along the banks of the Irawaddi in Ava, and in Perim Island in the Gulf of Cambay, showing that the same extinct fauna was formerly spread over the whole continent of India.

"This is not the place (say the discoverers) to enter upon the geological question of the age of the Sewalik strata; suffice it to say, that the general bearing of the evidence is, that they belong to the newer tertiary period. But another question arises: 'Are there any indications as to when this gigantic Tortoise became extinct? or are there grounds for entertaining the opinion that it may have descended to the human period?' Any *a priori* improbability that an animal so hugely disproportionate to existing species should have lived down to be a contemporary with man, is destroyed by the fact that other species of Chelonians which were

coeval with the *Colossochelys* in the same fauna, have reached to the present time; and what is true in this respect of one species in a tribe, may be equally true of every other placed under the same circumstances. We have as yet no direct evidence to the point, from remains dug out of recent alluvial deposits; nor is there any historical testimony confirming it; but there are traditions connected with the cosmogonic speculations of almost all Eastern nations having reference to a Tortoise of such gigantic size, as to be associated in their fabulous accounts with the elephant. Was this Tortoise a mere creature of the imagination, or was the idea of it drawn from a reality, like the *Colossochelys*? Without attempting to follow the tortoise tradition through all its ramifications, we may allude to the interesting fact of its existence even among the natives of America. The Iroquois Indians believed that there were originally, before the creation of the globe, six male beings in the air, but subject to mortality. There was no female among them to perpetuate their race; but learning that there was a being of this sort in heaven, one of them undertook the dangerous task of carrying her away. A bird (like the Garuda of Vishnoo, or the Eagle of Jupiter) became the vehicle. He seduced the female by flattery and presents: she was turned out of heaven by the supreme deity, but was fortunately received upon the back of a tortoise, when the otter (an important agent in all the traditions of the American Indians) and the fishes disturbed the mud at the bottom of the ocean, and drawing it up round the tortoise formed a small island, which, increasing gradually, became the earth. We may trace this tradition to an Eastern source, from the circumstance that the female is said to have had two sons, one of whom slew the other; after which she had several children, from whom sprung the human race.

"In this fable we have no comparative data as to the size of the tortoise; but in the Pythagorean cosmogony the infant world is represented as having been placed on the back of an elephant, which was sustained on a huge tortoise. It is in the Hindoo accounts, however, that we find the fable most circumstantially told, and especially in what relates to the second Avatar of Vishnoo, when the ocean was churned by means of the mountain Mandara placed on the back of the king of the tortoises, and the serpent Asokee used for the churning-rope. Vishnoo was made to assume the form of the tortoise, and sustain the created world on his back to make it stable. So completely has this fable been impressed on the faith of the country, that the Hindoos to this day even believe that the world rests on the back of a tortoise."

We ought to apologise to our readers, perhaps, for devoting so much space to the "vague and uncertain indications of mythological tradition:" we shall not, however, pursue the subject further, but merely state that the result at which the researches and inquiries of the discoverers arrived was, "that there are fair grounds for entertaining the belief as probable that the *Colossochelys*

Atlas may have lived down to an early period of the human epoch and become extinct since:—1st, from the fact that other Chelonian species and crocodiles, contemporaries of the *Colossochelys* in the Sewall fauna, have survived; 2nd, from the indications of mythology in regard to a gigantic species of tortoise in India."—*Ann. Nat. Hist.* vol. 15.

COLUBER: COLUBRIDÆ. An extensive genus and family of Ophidian reptiles, comprising all serpents whether venomous or not, whose scales beneath the tail are arranged in pairs; but now, according to Cuvier's arrangement, including only the harmless snakes, many of which habitually reside among trees, and are distinguished by the brilliancy of their colours and the gracefulness of their forms. [See SNAKES.]

COLUGO. The Flying Squirrel. [See GALEOPTHECUS.]

COLUMBIDÆ. A natural family of birds, comprising the pigeons, doves, and turtle-doves. In Britain there are four native species; the Ring-dove or Wood-pigeon; the Rock-pigeon, which is the original of all our domesticated breeds; the Stock-dove, which, like the Ring-dove, chiefly frequents coppices and groves; and the Turtle-dove, which is the smallest, and the most elegant both in form and colour. The *Columbidæ* fly well, and associate invariably in pairs; their nests are constructed in trees, or in the holes of rocks; and both parents sit upon the eggs. They are further remarkable for the peculiar mode in which their young are fed. The crop is furnished with numerous glands, which become developed in both sexes during incubation: these glands secrete a sort of milky substance, with which the food that passes into the crop is moistened; and the food, saturated with this secretion, is regurgitated by the parents for the nourishment of their young. By some naturalists these birds are regarded as forming a distinct order called *GYRATONES*. [See PIGEON.]

COLUMELLIDÆ. A family of univalve shells, distinguished by their having no canal at the base of the aperture, but a notch, more or less distinct, and plaits on the columella or left lip. Many individuals of this family, as *Mitra*, *Margarella*, *Voluta*, &c., are remarkable for their beauty.

COLYMBIDÆ. The *Colymbidæ*, or Divers, are a family of birds inhabiting the northern regions, and distinguished by their legs being placed so far back, that they always assume an erect position when standing. Their feet are large and webbed; they are rapid and powerful divers; and they feed both on fish and vegetables. [See DIVER.]

CONCHIFERA. The scientific name given to Bivalve Shells, which are separated into three orders: *Brachiopoda*; *Dimyaria*; and *Monomyaria*: [which see.] The Mollusca which inhabit them, not having any especial organs for seeing, hearing, or smelling, are limited to the perception of no other impressions but those of immediate contact.

deep red, and rising into a bifid, detached, crest-like membrane. The entire plumage is blue-black: its legs are dusky, with a tri-color ring or garter above the knee, red green, and yellow.

COPPER [BUTTERFLY]. A name applied by collectors to Butterflies of the genus *Lycaena*. [See LYCÆNA.]

COPRIDÆ. A family of Colcopterous insects allied to the Scarabæi. The name *Copris* is from the Greek word for dung, in which the insects are found. Some of them have the head and thorax singularly armed. They are generally of a dull black colour: but some of the species of the American ge-

BLUE AMERICAN DUNO-BEEBLE.
(*PHÆNEUS SAPPHIRINUS*)

nus *Phæneus* perfectly glow with rich green, red, and blue colours. Our figure, derived from Sturm's Catalogue, represents the brilliant blue *Phæneus sapphirinus* of Brazil. There are but few species of this family found in this country.

CORACIAS. A genus of Passerine birds. [See ROLLER.]

CORALLINA. The name given by Linnaeus to a genus or group of marine organized bodies, of the class *Vermes*, order *Zoophyta*. The animals of this genus are arborescent or tree-like in form; the stem fixed, with calcareous subdivided branches, mostly jointed. Neither pores nor polypes are distinguishable on the surface of these beings; and they were formerly supposed to be vegetable; but they give the most evident tokens of large portions of ammonia, the common test of animal substance, and have been often traced to spontaneous motion. Every tube, vesicle, or articulation, is probably the enclosure of a distinct animal, so that the entire mass or tree is a family; in this respect resembling the vegetable tree, in which every bud may also be regarded as an individual living plant. [See POLYTES, ACTINIA, &c.]

We may in this place very consistently introduce some observations made by late writers on Coral Reefs and Islands, the Coral Fishery, &c. With regard to the growth of coral, it has been observed, that many errors have prevailed upon this subject, both as to the rapidity of their extension, and the depth from which they are built up to the surface of the ocean. It has been commonly stated that many channels and harbours in the Red Sea have been closed up, within the memory of man, by the rapid increase of coral limestone. But Ehrenberg, who carefully examined these localities, attributes

the obstruction rather, in some instances, to the quantities of coral sand which have been washed into the harbours, and in others to the accumulation of ballast (generally composed of pieces of coral rock) thrown out from vessels. * * * There can be no doubt that, whether the growth of coral takes place as rapidly as some maintain, or as slowly as it is believed to do by others, it is among the most important of the progressive changes, which have been altering the surface of the globe since it has been tenanted by man. To it is due the existence of a large proportion of the islands of the Polynesian Archipelago, as well as many of those in the Indian Ocean; and the extent of these islands is far less than that of the reefs which are not yet raised above the level of the sea,—some presenting themselves at a distance from any upraised land, others fringing the shores of continents and islands, composed of other formations. It is not correct, however, to affirm (as has been frequently done) that these islands and reefs have been upreared by the Coral-polypes from the depths of the ocean. It is now satisfactorily ascertained that no known species can build from a greater depth than twenty fathoms; and a large proportion seem to prefer a depth of from twenty to thirty feet. As very deep water is found in the immediate neighbourhood of many of these reefs, the question arises, upon what basis they are constructed; and to solve this it is necessary to look at the forms which these massive structures present.

"A large proportion of the Coral Islands of the Polynesian Archipelago," as Dr. Carpenter observes, "are shaped like a crescent, sometimes like a complete ring; and these islands never rise many feet above the surface of the ocean. The highest part is always on the windward [easterly] side, against which the waves are almost constantly dashing. Within the crescent or ring is a basin, termed a lagoon; and this usually communicates with the open sea, by a channel, sometimes of considerable width, on the leeward side of the island. Occasionally this channel is completely filled up by the growth of the coral; and the lake, thus inclosed, only communicates with the sea by filtration through the Coral rock. The Coral-polypes never build above low-water mark; and they are not, therefore, immediately concerned in the elevation of the surface from beneath the waves. This is principally accomplished by the action of the sea itself. Large masses are often detached, by the violence of the waves, from the lower part of the structure; and these (sometimes measuring six feet by four) are washed up on the windward side of the reef. Shells, coral-sand, and various other debris, accumulate upon it in like manner, until it is at last changed into an island, upon which there is a calcareous soil capable of supporting various kinds of vegetation. When these have once established themselves, the elevation of the surface continues with greater rapidity,—successive layers of vegetable mould being deposited by the rapid and luxuriant vegetation of these tropical islands, which

are soon tenanted by various forms of animals, and at some subsequent period afford a habitation to Man."

Speaking of an island which was evidently of coral origin, Capt. Flinders thus reasons: "It seems to me, that when the animalcules which form the corals at the bottom of the ocean cease to live, their structures adhere to each other, by virtue either of the glutinous remains within, or of some property in salt water; and the interstices being gradually filled up with sand and broken pieces of coral washed by the sea, which also adhere, a mass of rock is at length formed. Future races of these animalcules erect their habitations upon the rising bank, and die in their turn to increase, but principally to elevate, this monument of their wonderful labours. The care taken to work perpendicularly in the early stages, would mark a surprising instinct in these diminutive creatures. Their wall of coral, for the most part in situations where the winds are constant, being arrived at the surface, affords a shelter, to leeward of which their infant colonies may be safely sent forth: and to this their instinctive foresight it seems to be owing, that the windward side of a reef, exposed to the open sea, is generally, if not always, the highest part, and rises almost perpendicular, sometimes from the depth of 200, and perhaps many more fathoms. To be constantly covered with water seems necessary to the existence of the animalcules, for they do not work, except in holes upon the reef, beyond low-water mark; but the coral sand and other broken remnants thrown up by the sea adhere to the rock, and form a solid mass with it, as high as the common tides reach. That elevation surpassed, the future remnants, being rarely covered, lose their adhesive property; and remaining in a loose state, form what is usually called a *key* upon the top of the reef. This new bank is not long in being visited by sea birds, salt plants take root upon it, and a soil begins to be formed; a cocoa nut, or the drupe of a pandanus is thrown on shore; land birds visit it, and deposit the seeds of shrubs and trees; every high tide, and still more every gale, adds something to the bank; the form of an island is gradually assumed; and last of all comes man to take possession."

A few words in this place respecting the CORAL FISHERY may not be inappropriate. The manner of fishing being nearly the same wherever coral is found, it will suffice to state the method adopted by the French, under the direction of the company established at Marseilles. Seven or eight men go in a boat commanded by the proprietor; and when the net is thrown by the caster, the rest work the vessel, and help to draw the net in. The net is composed of two rafters of wood tied crosswise, with leads fixed to them: to these they fasten a quantity of hemp twisted loosely round, and intermingled with some loose netting. This instrument is let down where they think there is coral, and pulled up again; when the coral is strongly entangled in the hemp and netting. For this, six boats are sometimes required; and if, in

hauing, in, the rope happens to break, the fishermen run the hazard of being lost. Before the fishers go to sea they agree for the price of the coral; and they engage, on pain of corporal punishment, that neither they nor their crew shall embezzle any, but deliver the whole to the proprietors. Red Coral is found in the Mediterranean, on the shores of Provence, about the isles of Majorca and Minorca, on the south of Sicily; on the coast of Africa; and, lastly, in the Ethiopic Ocean, and about Cape Negro. The divers say that the little branches are found only in the caverns whose situation is parallel to the earth's surface, and open to the south.

CORBULA. A genus of marine Mollusca, some species inhabiting the British coasts. Shell regular, inequivalve, and inequilateral, scarcely gaping; one cardinal spoon-shaped tooth in each valve, but no lateral; ligament interior. These small shells are met with in the seas of New Holland, China, and South America.

COREIDÆ. A family of Hemiptera, of which there are a few brown coloured species in this country; in tropical climates, where there is a luxuriant vegetation, they abound, and from their size, and frequently grotesque shapes, as may be seen in the British Museum collection, are very striking. In the example figured (*Diactor bilineatus*), a native

LEAF-LEGGED COREUS
(*DIACTOR BILINEATUS*)

of Brazil, the hind legs have singular leaf-like appendages to their tibial joints. This, however, is common to many other species. The smell of these insects is peculiar; the word *cimicine* may be used to express it; it is very far from agreeable, and has associations connected with it by no means pleasing.

COREGONUS. The *Guinad*. A genus of Malacopterygious fishes, belonging to the *Salmonidæ* family, distinguished by a small trout-like mouth, but with few teeth, and sometimes none; the scales rather large; and the dorsal fin short. There are many species of this genus, some in the sea, others in the fresh waters only. It feeds on insects, and minute fresh-water Crustacea.

They seem to abound in the Arctic parts

of North America; one especially we may mention, the *Coregonus albus*, called the *White-fish* by the fur traders, and *Poisson blanc* by the Canadians. It is from seventeen to twenty inches long. It is bluish-grey on the back, lighter on the sides, and white on the belly; the scales are large and orbicular; there are about eighty scales on the lateral line, and twenty in an oblique series from the dorsal. This species in particular abounds in the lakes of North America. Dr. King, speaking of it, says, "Take, for instance, the white-fish only—the *Coregonus albus*, which has never failed to yield to the fisherman's net every demand—the bread of life to the inhabitants of North America, as I have called it, in gratitude for its being the provision which saved my party when in search of Sir John Ross from the death of starvation. This is a food upon which man will not only live for several months together, but actually fatten."

CORMORANT. (*Phalacrocorax*.) Among the whole of the web-footed birds which prey on fish, there are none so voracious as Cormorants. They are most excellent divers, and pursue their prey with astonishing facility beneath the surface of the water, but

COMMON CORMORANT.
(*PHALACROCORAX CARBO*)

upon land they are extremely awkward in their movements, owing to their legs being placed so far backwards: they, however, fly with rapidity; and their tail being rather long and furnished with strong feathers, it helps to support their body while walking. As soon as winter approaches, they are seen dispersed along the sea-shores, entering the mouths of fresh-water rivers, and threatening destruction to all the finny tribe. There are several species, but a description of the one common in this country will be sufficient for our purpose. This, which is called by Bewick, the Great Black Cormorant, is said to vary from four to seven pounds in weight, and the size from thirty-two inches to three feet four or five in length, and from four feet to four feet six inches in

breadth when the wings are extended. The bill, to the corners of the mouth, measures four inches, and on its ridge two inches and three quarters: it is of a dark horn colour, and the tip of the upper mandible is much hooked and sharp: the lower bill is compressed, and covered about the gape of the mouth with a naked yellowish skin, extended under the chin and throat, where it hangs loose, and forms a kind of pouch, which is capable of distention to a great width: the skin about the eyes is also naked and yellowish, and the eyes have a remarkably wild stare. The crown of the head and the neck are black; and on the former are some loose feathers, which form a sort of short crest; the breast, all the under parts, and the rump, are black glossed with green; the quills and tail-feathers are black; the legs black.

The Cormorant is found in every climate. In Greenland, where it is said they remain throughout the year, the jugular pouch is made use of by the natives as a bladder to float their fishing-darts, after they are thrown; their skins, which are tough, are used by them for garments, and their flesh, which is rank and disagreeable, for food. They usually assemble in flocks on the inaccessible parts of the rocks which overhang or are surrounded by the sea; upon which the female makes her nest of withered sea-weeds, sticks, and grasses: she lays four or more greenish-white eggs, about the size, but somewhat longer, than those of a goose. At sea, or on the inland lakes, they make a terrible havoc. From the greatest height they drop down upon the object of pursuit, dive after it with the rapidity of a dart, and, with an almost unerring certainty, seize the victim; then emerging, with the fish across the bill, with a kind of twirl, throw it up into the air, and dexterously catching it head foremost, swallow it whole.

Notwithstanding the natural wildness of their disposition, it seems that certain species of these birds have formerly been tamed and rendered subservient to the purposes of man, both in this and in other countries. Among the Chinese, it is said, they have frequently been trained to fish, and that some fishermen keep many of them for that purpose, by which they gain a livelihood. In England too, formerly, according to Willoughby, they were hoodwinked in the manner of the falcons, till they were let off to fish, and a leather thong was tied round the lower part of their necks, to prevent their swallowing the fish. The whole department of the Cormorant indicates the wary circumspect plunderer, the unrelenting tyrant, and the greedy insatiable glutton, rendered lazy only when the appetite is palled; it ought, however, to be observed, that this bird, like other animals, led only by the cravings of appetite, and directed by instinct, fills the place and pursues the course assigned to it by nature.

It may be thought that we have already dwelt at sufficient length on the nature and habits of the Cormorant; nor would we trespass farther but for the pleasure it affords us to quote from that inimitable writer

Mr. Waterton, whose pleasing descriptions are seldom deficient either in bold originality or graphic power. Walton Hall, the seat of this gentleman, has long been a perfect asylum for such of the feathered tribes as have the good fortune to make it their permanent abode; and he may therefore well say, while pleading their cause [see the Preface to his *Essays*]:—"I possess the very best opportunities of observing the birds whose habits I have described." "The Cormorants," he observes, "often pay me a visit in the winter season; and could they but perceive that there is safety for them here, and great danger elsewhere, they would remain with me while the water is unfrozen. But they wander, unfortunately, through parts where protection is not afforded them; and, being outlandish birds in the eyes of the neighbouring game-keepers, they are immediately shot at. Those which find their way here are so unconscious of danger, that, after they have spent a considerable portion of time in diving for fish, they will come and preen their feathers on the terrace which rises from the water, within ten yards of the drawing-room windows."

"The Cormorant may be justly styled the feathered terror of the finny tribe. His skill in diving is most admirable, and his success beyond belief. You may know him at a distance, among a thousand water-fowl, by his upright neck, by his body being apparently half immersed in the water, and by his being perpetually in motion when not on land. While the ducks and teal and widgeons are stationary on the pool, the Cormorant is seen swimming to and fro, 'as if in quest of something.' First raising his body nearly perpendicular, down he plunges into the deep; and, after staying there a considerable time, he is sure to bring up a fish, which he invariably swallows head foremost. Sometimes half an hour elapses before he can manage to accommodate a large eel quietly in his stomach. You see him straining violently, with repeated efforts to gulp it; and when you fancy that the slippery mouthful is successfully disposed of, all on a sudden the eel retrogrades upwards from its dismal sepulchre, struggling violently to escape. The Cormorant swallows it again; and up again it comes and shows its tail a foot or more out of its destroyer's mouth. At length, worn out with ineffectual writhings, and slidings, the eel is gulped down into the Cormorant's stomach for the last time, there to meet its dreaded and inevitable fate. This gormandizing exhibition was witnessed here by several individuals, both ladies and gentlemen, on Nov. 26. 1832, through an excellent eight and twenty guinea telescope; the Cormorant being, at that time, not more than a hundred yards distant from the observers. I was of the party." [For other species, such as the Chinese Fishing Cormorant and the Australian Cormorant, see *PHALACROCORAX*.]

CORVIDÆ. The Crow tribe; a family of birds which belong to the *Corviostres*. The *Corvidæ* are very widely diffused over the globe; the general characters are con-

sequently well known. They have a strong bill, compressed at the sides, and covered at the base with stiff feathers, which advance forwards so as to cover the nostrils; the bill is capable of laying hold of almost any kind of food, and the stomach of digesting it. The form of their foot adapts them to traverse the fields and pastures with facility, in search of food; whilst they can also perch with security on trees, the tarsi and toes being moderately long and stout, and the claws arched and acute. Their wings are of that form which ensures a powerful and regular flight; steady without being heavy, and buoyant without wavering; for they are broad and moderately long, and usually rounded at their extremities. The tail, which is chiefly used as a rudder to direct the course of the bird in rapid flight, is short in the species that seek their food entirely on the ground, and long in those which reside chiefly in trees and bushes. Their sight is keen and distant; they often show great sagacity in their natural actions; they possess much docility; and their courage and activity are only equalled by their caution and vigilance. In most of the species inhabiting temperate climates their plumage is rather sombre; but though dark in hue, it is lustrous; while many species in tropical climates exhibit considerable brilliancy and variety in their colouring. [See *Crows*.]

CORYPHODON. [See SUPPLEMENT.]

COSSUS. A genus of nocturnal Lepidoptera, the larvæ of which feed on wood.

COSSUS LIGNIPERDA, or GOAT MOTH. This is one of the largest European Moths, being nearly three inches in the expansion of its fore-wings, the colour of which is ashy white, clouded with brown, and marked with an infinite number of short, black, irregular streaks, forming a kind of network: the hind wings are brown, with darker reticulations extending along the margins. The thorax is ochre-coloured in front, pale in the middle, and with a black bar behind: abdomen brown, with the margins of the segments pale yellowish grey.

GOAT MOTH.—(*COSSUS LIGNIPERDA*.)

The Caterpillar, which is nearly as large as a man's finger, is of a dull fleshy hue, with dark chestnut scales on the back of each segment, and a few scattered hairs. It chiefly feeds upon willows and poplars, but will attack various other trees, boring into the

timber, and frequently doing very serious damage. It forms a rough cocoon of the chips of wood, which it has bitten to pieces,

CATERPILLAR OF THE GOAT MOTH

fastening them together with a glutinous secretion, and lining them with its silken web. The pupa has the head-case acute, and each of the abdominal segments is furnished with several rows of reflexed spiny hooks; by the aid of which the pupa, shortly before arriving at the perfect state, is enabled to push itself through its cocoon, and to the surface of the tree; out of the aperture of which the exuviae may be seen partially sticking after the moth has made its escape.

PUPA AND COOCON OF THE GOAT MOTH.

The strength of their jaws is so great that they will very soon destroy any common chip-box in which the larva may be placed, by abrading the edges, to gain its liberty. In breaking up decayed pollards, we not unfrequently find this grub in all the stages of its growth; but more generally observe them without inhabitants, yet perforated with holes large enough to admit the finger. "I suspect," says Mr. Knapp, "that these anger worms are the primary cause of the decay of the tree; having often observed their perforations, and found them, both large and small, in the solid spur or root of the tree, when the upper portion, having been bored, and in a state of decline, is abandoned by them. Those that are full fed appear to form their cases in that part which has lost coherency, while the younger and imperfect creatures mine their way, and obtain nutriment in the solid timber, thus killing the tree by inches; when rain and moisture find lodgment, and complete the dissolution. One year's preparation is the period usually assigned to the larvæ of most insects, before they arrive at their perfect state; but by the Goat-Moth three years are required before

it attains its winged state from the egg. Consequently, for the larger portion of its life it is occupied in these destructive operations; and thus this creature becomes a very powerful agent in reducing these Titans of the vegetable world, crumbling them away to their original dust: for what was decreed to be the termination and punishment of Man, is found in active operation throughout the whole chain of Nature's works, which are but dust, and unto dust return, continuing an endless series of production and decay, of restoration and of change."

We may mention, that one of the most extraordinary works on Natural History ever published is devoted to the anatomy of this insect. It is by Lyonet. It will be sufficient to state, in order to give some idea of the careful manner in which the anatomy of this caterpillar has been studied by him, that the author of the "*Traité Anatomique*" discovered not fewer than 4031 muscles in its body; 223 being attached to the head, 1647 to the body, and 2186 to the intestines, whereas in the human body only 529 have been discovered; so that this caterpillar possesses nearly eight times as many muscles as are contained in the human frame! It has an offensive smell, from which it derives its popular English name.

CORYPHÆNA. A genus of Acanthopterygious fishes, family *Scombridae*; sometimes called *Dolphin*, but not to be confounded with the Dolphin proper, which belongs to the *Cetacea*. The principal characters by which they are distinguished are as follows:—Body elongated, compressed, covered with small scales; dorsal fin extending nearly the whole length of the back; the tail more or less forked, and the pectoral fin usually arched above and pointed. They have the head much elevated, and the palate and both jaws furnished with teeth. These fishes are very rapid in their motions, generally of large size, and they prey upon the flying-fish. The greater part inhabit the Mediterranean. [See *DOLPHIN*.]

COTTIDÆ. A family of Acanthopterygious fishes, with hard or mailed cheeks; the sub-orbitals being united to the preoperculum, and so expanded as to cover a large part on the whole of the cheeks. They have many characters in common with the *Percidæ*; in short, a family likeness prevails among the fish possessing this cheek-mail, notwithstanding the various forms of the head that result from its greater or less development. In one group of genera, the head has the form of a cube; in another it is round; in a third it is compressed; and a fourth group is composed of fish of hideous aspect, with a monstrous head and vertical eyes. The only forms among the *Cottidæ* that have anything like a general distribution are the larger genera of *Trigla*, *Cottus*, *Aspidophorus*, *Scorpena*, *Sebastes*, and *Gasterosteus*, containing the majority of the whole species. The range of individual species is more remarkable in this family than in the more extensive one of *Percidæ*; as is evident when we consider the number of species which cross the Atlantic; and in this

respect there is some analogy between the *Cottidae* and some of the higher classes of animals; it having been observed that the quadrupeds and birds common to the Old and New Worlds are species that have a high northern range.—*Sir John Richardson, M. D., Fauna Bor. Amer.*

COTTUS. A genus of Acanthopterygious fishes, chiefly characterized by having a large head, furnished more or less with spines or tubercles. [See BULL-HEAD.]

COW. The female of the Bovine species, and the most valuable to man of all ruminating quadrupeds. [See OX.]

COW-BUNTING. (*Molothrus pecoris.*) A well-known Passerine bird in North America, the most remarkable trait in the character of which is, the unaccountable practice it has of dropping its eggs into the nests of other birds, instead of building and hatching for itself; and thus entirely abandoning its progeny to the care and mercy of strangers. "About the 25th of March, or early in April," says Wilson, "the cowpen bird makes his first appearance in Pennsylvania from the south, sometimes in company with the red-winged blackbird, more frequently in detached parties, resting early in the morning, an hour at a time, on the tops of trees near streams of water, appearing solitary, silent, and fatigued. They continue to be occasionally seen, in small solitary parties, particularly along creeks and banks of rivers, so late as the middle of

consequent loss of the egg thus dropt in it by the intruder. But when the owner herself has begun to lay, and there are one or more eggs in the nest before the Cow-Bunting deposits hers, the attachment of the proprietor is secured, and remains unshaken until incubation is fully performed, and the little stranger is able to provide for itself. * * * I have never known more than one egg of the Cow-Bunting dropt in the same nest. This egg is somewhat larger than that of the blue-bird, thickly sprinkled with grains of pale brown on a dirty whiteground. It is of a size proportionable to that of the bird."

"What reason Nature may have for this extraordinary deviation from her general practice is, I confess, altogether beyond my comprehension. There is nothing singular to be observed in the anatomical structure of the bird that would seem to prevent, or render it incapable of incubation. The extreme heat of our climate is probably one reason why, in the months of July and August, they are not to be seen here. Yet we have many other migratory birds that regularly pass through Pennsylvania to the north, leaving a few residents behind them; who, without exception, build their own nests and rear their own young. This part of the country also abounds with suitable food, such as they usually subsist on. Many conjectures, indeed, might be formed as to the probable cause; but all of them that have occurred to me are unsatisfactory and inconsistent. Future, and more numerous observations, made with care, particularly in those countries where they most usually pass the summer, may throw more light on this matter; till then, we can only rest satisfied with the reality of the fact."

The length of this species is seven inches, breadth eleven inches; the head and neck is of a very deep silky drab; the upper part of the breast a dark changeable violet; the rest of the bird is black, with a considerable gloss of green when exposed to a good light; the tail is slightly forked; legs and claws, glossy black, strong, and muscular; iris of the eye, dark hazel. The young male birds are at first altogether brown, and for a month or more are naked of feathers round the eye and mouth; the breast is also spotted like that of a thrush, with light drab and darker streaks. In about two months after they leave the nest, the black commences at the shoulders of the wings, and gradually increases along each side, as the young feathers come out, until the bird appears mottled on the back and breast with deep black, and light drab. At three months the colours of the plumage are complete, and, except in moulting, they are subject to no periodical change.

COWRIES. A genus of shells used in the East Indies, and many parts of Africa, as the current coin of the natives. [See CYPREA.]

COW-FISH. [See MANATUS.]

COYPU. (*Myopotamus coypus.*) A South American rodent animal, resembling the

COW-BUNTING.—*MOLOTHRUS PECORIS.*

June; after which we see no more of them until about the beginning or middle of October, when they re-appear in much larger flocks, generally accompanied by numbers of the redwings; between whom and the present species there is a considerable similarity of manners, dialect, and personal resemblance. In these aerial voyages, like other experienced navigators, they take advantage of the direction of the wind, and always set out with a favourable gale."

"It is well known to those who have paid attention to the manners of birds, that, after their nest is fully finished, a day or two generally elapses before the female begins to lay. This delay is in most cases necessary to give firmness to the yet damp materials, and allow them time to dry. In this state it is sometimes met with, and laid in by the Cow-Bunting, the result of which I have invariably found to be the desertion of the nest by its rightful owner, and the

beaver in many respects, though of a smaller size. Its head is large and depressed; ears small and rounded; muzzle pointed, with long stiff whiskers. Its hind feet are webbed, and its habits are aquatic; it swims with

COYPU.—(MYOPOTAMUS COYPUS.)

great ease, lives in the vicinity of water, and burrows in the ground. Its tail is round, instead of being flattened like the beaver, and its scaly covering is partly concealed by scattered hairs. It is easily domesticated, and its manners in captivity are very mild. The Coypu has two kinds of fur: long ruddy hair, which gives the tone of colour; and a brownish ash-coloured fur at its base, which, like that of the beaver, is used largely in the manufacture of hats. It is believed that about 800,000 skins of this animal, under the name of *Neutria* skins, have sometimes been imported into Britain from South America in the course of a year. There is, or was lately, in the gardens of the Zoological Society, a live specimen of this water-loving creature, which enjoyed itself much by diving, while the ease and grace of its manners could not but gratify the visitors.

CRAB. (*Cancer*.) The name of a considerable group of invertebrate animals, whose bodies are covered by an external skeleton, or calcareous crust, having ten articulated limbs, adapted for swimming or walking, and breathing by gills. The head and corselet are united, the latter being broader than it is long; the tail is short in proportion, and concealed by being turned forward beneath the body. They belong to the section of ten-legged, short-tailed Crustacea (*Decapoda brachyura*) of the latest systems, and are of numerous species, exceedingly various in size, colour, and modes of living. The sense of sight, in most of the species, is peculiarly acute, and enables them to distinguish the approach of objects from a very considerable distance. But they are mostly remarkable for a complex and elaborate apparatus for mastication. The mouth is furnished with at least eight pieces or pairs of jaws, which pass the food through an extremely short gullet into a membranous stomach of considerable size. This stomach is rendered curious by having within certain cartilaginous appendages, to which strong grinding teeth are attached. These are five in number, and placed at the pyloric extremity, or outlet of the stomach, so that the aliment, after being subjected to the action of the jaws, is again more perfectly chewed by the stomach-teeth, before entering the

digestive tube, where it is exposed to the action of the biliary fluid of the liver. The latter organ is of great size in these creatures, and is all that soft, rich, yellow substance, found immediately beneath the superior shell, called the *fat of the Crab*. A little posterior to the stomach (commonly called *sand-bag*), the heart is situated,—a somewhat globular, whitish body, which propels a colourless lymph to the gills (called *dead men's fingers*) and rest of the body, whence it is brought back to the heart by a hollow vein (*vena cava*) of considerable size.

The process of sloughing, moulting, or throwing off the entire calcareous covering which constitutes their only skeleton, is common to all the Crustacea, and is very worthy of attention. As it is obvious that the hard shell, when once perfected, cannot change with the growth of the animal, it becomes necessary that it should be shed entirely; and this shedding takes place at regular periods, at which the increase of size occurs. No one can behold the huge claws or forceps of various species, and the smallness of the joints between them and the body, without feeling some surprise that the creature should be able to extricate them from the old shell, though this is readily accomplished. The aquatic Crabs, when the season of shedding arrives, generally seek the sandy shores of creeks and rivers, and, having selected a situation, they remain at rest, and the change begins. The body of the Crab seems to swell, the large upper shell is gradually detached at the edge, or where it joins the thorax or corselet, and the membrane gradually gives way, and rises up from behind, somewhat like the lid of a chest. The Crab next begins to withdraw the limbs from their cases, and the large muscles of the claws undergo a softening, which allows of their being drawn through the smaller joints. This movement is slowly effected, and, at the time it is accomplished, the parts about the mouth, the antennae, and eyes, are withdrawn from their old cases, and the animal escapes, retaining its original figure, but soft, helpless, and incapable of exertion or resistance. By a gentle and not very obvious motion, we next observe the sand displaced below the body, and the Crab begins to be covered with it, until, at length, he is sufficiently covered for safety, though still in sight. This is generally in shallow water, where the sun shines freely upon the bottom; and, in the course of twelve hours, the external membrane begins to harden, so as to crackle like paper when pressed upon, and the process of hardening goes on so rapidly, that, by the end of the next forty-eight hours, the Crab regains something of his former solidity and ability to protect himself by flight or resistance.

The habits of Crabs are very various: some are exclusively aquatic, and remain on the sands or rocks, at great depths in the sea; others inhabit excavations formed in the soft coral reefs or bars on certain coasts; some spend their days altogether on shore, living in burrows or dens, formed in a moist or boggy soil; others resort to the rocky flats

or beaches, to bask in the sun, where only an occasional wave dashes over them, and seek refuge in the sea when alarmed; while some species are completely terrestrial, inhabiting holes upon the highest hills and mountains of the West Indies.

Of these LAND CRABS the most remarkable is the species formerly so abundant in the highlands of Jamaica (*Gecarcinus ruricola*), and still common in less densely peopled or uninhabited islands. When the season for

JAMAICA LAND CRAB.
(*GECARCINUS RURICOLA*.)

spawning arrives, vast armies of them set out from the hills, marching in a direct line towards the sea-shore, for the purpose of depositing their eggs in the sand. On this grand expedition nothing is allowed to turn them from their course. With unyielding perseverance they surmount every obstacle which may intervene, whether a house, rock, or other body, not avoiding the labour of climbing by going round, but ascending and passing over it in a straight line. Having reached the destined limit of their journey, they deposit their eggs in the sand, and recommence their toilsome march towards their upland retreats. They set out after nightfall, and steadily advance, until the approach of daylight warns them to seek concealment in the inequalities of the ground, or among any kind of rubbish, where they lie ensconced until the stars again invite them to pursue their undeviating course. On their seaward journey they are in full vigour and fine condition; and this is the time when they are caught in great numbers for the table. Their flesh, which is of the purest whiteness, is highly esteemed, but, like that of all crustaceous animals, is rather difficult of digestion. Returning from the coast, they are exhausted, poor, and no longer fit for use. They then retire to their burrows, where they slough or shed their shells; a short time after which operation, and while in their soft state, they are considered by epicures as most delicious, and are consequently sought for with avidity.

Those Crabs which take up their abode in the vicinity of sugar-cane fields are very injurious to the planter; some of the species being particularly fond of the cane, the juice of which they suck and chiefly subsist on. They are of course narrowly watched, and no opportunity of catching them is lost sight of; but such is the wonderful facility they have in running, or rather darting in any direction, or with any part of their bodies foremost, that they are almost always enabled to elude capture. It is seldom, however, that they go far from their burrows in the day-time; and their vigilance is such

that they regain them in a moment, and disappear securely, as soon as a man or dog comes near enough to be seen.

Many of the habits of these animals have attracted the notice of travellers. Dr. Gardner, in his "Travels in Brazil," says that while he was near Rio San Francisco,

LAROE-CLAWED CALLING CRAB
(*GELASIMUS*.)

he amused himself "by watching the operations of a small species, belonging to the genus *Gelasimus*, that was either making or enlarging its burrow in the sand. About once in every two minutes it came up to the surface with a quantity of sand enclosed in its left claw, which, by a sudden jerk, it ejected to the distance of about six inches, always taking care to vary the direction in which it was thrown, so as to prevent its accumulation in one place."

Another species of Land Crab, apparently belonging to the genus *Thelphusa*, which inhabits India, is thus noticed by Bishop Heber, in his Journal:—"All the grass through the Deccan generally swarms with a small Land Crab, which burrows in the ground and runs with considerable swiftness, even when encumbered with a bundle of food as big as itself: this food is grass, or the green stalks of rice; and it is amusing to see the Crabs, sitting, as it were, upright, cut their hay with their sharp pincers, and then waddling off with their sheaf to their holes, as quickly as their sidelong pace will carry them." They have been found on the table-lands, at an elevation of nearly 4000 feet; but it is believed that they do not perform an annual migration to the sea, for the purpose of depositing their eggs.

CRABRO: CRABRONIDÆ. A genus and family of Hymenopterous insects, popularly known as Wood-wasps. Most of the larger species are marked with yellow rings; the smaller are generally wholly black. They are extremely active in their movements, and may be seen busily employed, in the hottest sunshine, extracting nectar from the flowers of plants, or running about in search of other insects, on which they prey. They excavate cells in the ground, or in rotten posts, timber, &c., in which they deposit their eggs, together with the flies, &c., which constitute the food of the larvæ when hatched. Many species are found in this country: we refer our readers who may wish further acquaintance with them, to the capital work of Mr. Shuckard on the Indigenous Fossorial Hymenoptera.

CRACIDÆ. A family of Galliaaceous birds, peculiar to tropical America, which

approach the turkey in size and grandeur of appearance. They live in the woods, feed on berries, &c., and build on trees; but they are easily domesticated, and their flesh is exceeded by no fowl in delicacy and whiteness. [See CURASSOW.]

CRACTICUS. [See CROW SHRIKE.]

CRAKE. The CORN-CRAKE, or LAND-RAIL, (*Ortyx vetula crax*), which is very similar to the Water-rail, is fond of woody places, and high herbage or corn-fields in the vicinity of water, or in marshy places, where it breeds; making its nest of a few dry plants, put carelessly together, and laying ten or twelve eggs of a dull white, marked with rust-colour spots. The bill is short, strong, and thick; all the feathers on the upper part of the plumage are of a dark brown, edged with light bay; the wing-coverts and quills are deep chestnut; the fore parts of the neck and breast are pale cinereous; the belly is a yellowish-white; and the legs are a pale flesh-colour. It is much sought after for the delicacy of its flesh, but it is a difficult bird to spring. The legs, which are remarkably long for the size of the bird, hang down while it is on the wing; and, in general, it seems rather inclined to swiftness of foot than rapidity of flight. It is migratory, appearing in England about the beginning of April, and departing in October. At the time of its arrival the bird is extremely lean; but before it quits the island it becomes excessively fat. Its food is chiefly worms, snails, and insects; but it also occasionally feeds on seeds and various vegetables. Its note (crek-crek-crek), rapidly repeated, has been compared to the noise made by drawing a finger along the teeth of a comb.

CRAMP-FISH. A name by which the Torpedo is sometimes called. [See TORPEDO.]

CRANE. Birds of the Crane kind (family *Gruidæ*) subsist on herbs, seeds, worms, frogs, and slugs: they reside in marshy places, rarely visiting the sea shores, and are found in various parts of the world; but only one, the COMMON CRANE, (*Grus cinerea*), is a native of Europe. This bird frequently measures upwards of five feet in length, and weighs about ten pounds; its gait is erect, and its figure tall and slender. The bill is about four inches long, straight, pointed, and compressed at the sides, of a greenish-black, turning lighter towards the point; tongue broad and short, and horny at the top. The forehead, to the middle of the crown, is covered with black hairy down, through which the skin appears red; behind this it is nearly bare to the neck, which is ash grey. The sides of the head behind the eyes, and the hinder part of the neck, are white. The space between the bill and eyes, the cheeks, and fore part of the neck, are a blackish ash; greater wing-coverts also blackish; and those farthest from the body, with the bastard wing and quills, quite black: the rest of the plumage is a fine waved light ash. From the pinnon of each wing springs an elegant tuft of loose feathers, curled at the

ends, which fall gracefully over the tail, in their flexibility, position, and texture, resembling the plumes of the ostrich. The legs and bare part of the thighs are black.

The Crane is migratory, and, soaring high in the air, performs the boldest and most distant journeys. In summer they spread themselves over the north of Europe and Asia as far as the arctic circle; and in the winter they are met with in India, Syria, Egypt, &c. They formerly visited the fens and marshes of this country in large flocks; but they seem to have been driven away by the advance of cultivation, which has elsewhere, as here, deprived it of many of its most congenial localities. The female lays two greyish-green eggs, spotted with brown.

The SIBERIAN CRANE (*Grus gigantea*) inhabits the great marshes and lakes of Siberia: it builds its nest, of herbs and grass, in almost inaccessible situations amongst the reeds; where the female lays two eggs: both sexes are said to watch the nest alternately; and during the period of incubation, although they are very shy at other times, they will boldly attack any person that approaches their haunts. This species is four feet six inches in height; the bill large and red; the face naked beyond the eyes, and of a red colour; the greater quills and their coverts deep black, the rest of the plumage snowy white; the tail nearly even; the legs red.

The BROWN CRANE (*Grus Canadensis*) is a native of North America, migrating northward in the spring to breed, and returning to the south in autumn. It is three feet three inches long, and its beak about four inches, the tip of the under mandible being of a pale flesh-colour: the top of the head being covered with a red skin, thinly beset with hairs; the hinder part and neck, grey; the scapulars and wing-coverts, pale rufous, margined with brown; the belly, breast, sides, and thighs, ash-colour: the wing-coverts next the body, grey, forming a band on the wing; the greater quills dark brown, with white shafts; the secondaries pale rufous; the tail of a deep ash-colour; the legs and bare part of the thighs, black. The female lays two very large and long eggs at a time; they are much pointed at one end, and freckled with brown. The nest is formed on a tuft upon which much dry grass is accumulated, until it becomes as high as the belly of the bird when standing; this is covered at the top with very fine dried grass, upon which the eggs are laid, and the female stands over them, placing her legs on each side of the heap. [See DEMOISELLE.]

CRAWFISH, or CRAYFISH. (*Astacus fluviatilis*.) A Crustaceous animal of the genus *Astacus*, differing in general appearance but little from the Lobster. They are found in almost every river, and even brook, in England; and their flesh is reckoned cooling and nutritious. Species of this genus are found in all parts of the world. In the mammoth caves of Kentucky, in the United States, a species has been discovered; it is the *Astacus pellucidus* of Tellkamp. Mr.

Virtue has written a paper on this subject, and on the other curious animal productions of these caves; to which we refer our readers.

CREEPER. (*Certhia*.) A numerous genus of insectivorous birds, distinguished for the most part by being adapted to live upon the trunks and branches of trees, and to feed upon the insects which infest the bark. The form of the bill is, in some, long and slender; in others, short and stout, and capable of penetrating very hard substances. They have a long, slender, arched bill; wings long and rounded; feet rather slender, but the hinder toe is long and stout; and the tips of the tail-feathers extend beyond the webs. In the splendour and variety of their colours the Creepers rival the Humming-birds, to which they are nearly allied in some of the smaller species. These birds cling by their feet to the perpendicular surface of trees, resting upon the stiff quills of their tails; and they will even pass round a horizontal branch, clinging to its under surface with their backs to the ground.

The **COMMON CREEPER** (*Certhia familiaris*) weighs only four drams, and next to the Crested Wren is the least of the British birds. The bill is hooked; the legs slender; the toes and claws very long. It breeds in

COMMON CREEPER — (*CERTHIA FAMILIARIS*.)

hollow trees; and lays from five to seven spotted ash-coloured eggs. The head and upper part of the neck are brown, streaked with black; the coverts of the wings are variegated with brown and black; the quill-feathers dusky, tipped with white, and barred; the breast and belly white; and the tail very long.

The **WALL CREEPER** (*Tichodroma muraria*) is considered as one of the rarer European birds, and its principal residence seems to be in Italy and Spain, where it is observed to frequent ruins, creeping about the mutilated walls in quest of spiders and other insects. Its colour is a deep bluish-grey; the wing-coverts and middle quill-feathers black, those nearest the body edged with white; the tail short and black, the two exterior feathers on each side being tipped with white.

CRICKETS. (*Achetidae*.) A group of Orthopterous insects, belonging to the *gryl-*

loid family, which comprises "the crickets of the hearth," the mole-crickets, and the grasshoppers. The Crickets are distinguished from the other members of this family by their long antennae, and by the comparative smallness of their thighs. Their bodies are short, thick-set, and soft, with the head, corselet, and abdomen of equal length and breadth: the elytra, which do not completely cover the belly, are curved squarely, and are not roof-shaped, as in the locust and grasshopper. In the winged species the wings exceed the elytra, and project even beyond the abdomen, in the form of a sort of bifid tail.

The Cricket's chirping noise, as it is called, is produced by the friction of the bases of

HOUSE CRICKET
(*GRYLLUS DOMESTICUS*)

their elytra, or wing-cases, against each other, these parts being curiously adapted to produce this sound. There are some people to whom the chirp of the **DOMESTIC CRICKET** is not merely an agreeable sound, but who regard the presence of these active insects as a good omen! For our own part, while we are ready to admit that they are perfectly harmless, when, issuing from their warm abodes, they skip round the hearth and join in their monotonous song, we confess that "we would much rather have their room than their company."

The **FIELD CRICKET** (*Acheta campestris*) is much larger, and also rarer, than the preceding: it is also more noisy. It is of a blackish colour, with a large head in proportion to the body, and full prominent eyes: it frequents hot sandy districts, in which it forms its burrow at the side of footpaths, &c., in situations exposed to the sun, to the depth of from six to twelve inches; and sits at the mouth of it, watching for its prey, which consists of other insects. [See *DEINACRIDÆ*: *GRYLLUS*: *MOLE CRICKET*.]

CRIMSON UNDERWING (*MOTHS*). A name applied by collectors to species of Moths, of the genus *Catocala*.

CREPIDULA. A genus of Molluscous animals, inhabiting an irregularly shaped shell, and often very much flattened; the inside partly covered with a plate, so as to resemble a half-decked boat. There are many recent species, and some fossil. The inside of the *Crepidula onyx* is of the most brilliant black, while the margin of the shell is tinged with a rich brown, and the little half-deck (if such it may be called) is of a

beautiful white. These shells are often found upon rocks, where they constantly remain, and form a very irregular outline at the circumference, agreeing with the shape

SLEEPER-SHELL—(CREPIDULA PORCELLANA.)

of the particular part to which they are attached. One species frequently fixes itself upon other living shells, particularly upon the *Purpura*, whose movements it of course follows. The specimen we have here figured is the *Crepidula porcellana*.

CRINOIDEANS. The name of an almost extinct class of invertebrate animals, having a radiated, lily-shaped disc, supported on a jointed stem; and having a crustaceous or coriaceous covering. When this stem is cylindrical, the species are termed *Encrinurus*; when it is pentagonal, *Pentocrinites*. (See *ENCINITES*, p. 219, and *PENTACHINUS*, p. 307.)

CRIOCERIS. A genus of Coleopterous insects, belonging to the family *Eupoda*. They live upon aquatic plants, asparagus, &c.; their larvæ feeding upon the same. They have the body soft, short, and swollen; and descend into the earth to become pupæ. One species, *Crioceris asparagi* (the Asparagus Beetle), is of a blue colour, with the thorax red, and the elytra yellowish-white with blue markings. In its larva state it feeds upon the young sprigs of asparagus, and is sometimes so abundant as to do considerable damage to the plants.

CRIOCERIDIDÆ. A group of oblong leaf-beetles, distinguished by the following characters. The eyes are nearly round and prominent; the antennæ are of moderate length, composed of short, nearly cylindrical or beaded joints, and are implanted before the eyes; the abdomen is narrow and almost cylindrical or square, rounded behind, and much wider than the thorax; and the thighs of the hind legs are often thickened in the middle.

Crioceris trilineata, or Three-lined Leaf-beetle (a North American species), will serve to exemplify the habits of the greater part of the insects of this family. Dr. Harris of Boston, in his truly original work on the Insects of Massachusetts, has described them at length, and it is principally from his work that we are indebted for our notice. This beetle is about one quarter of an inch long, of a rusty buff or nankin-yellow colour, with two black dots on the thorax, and three black stripes on the back, namely, one on the outer side of each wing-cover, and one in the middle on the inner edges of the same; the antennæ (except the first joint) and the feet are dusky; the thorax is

abruptly narrowed or pinched in on the middle of each side. When held between the fingers, these insects make a creaking sound like the Capricorn-beetles. They appear early in June on the leaves of the potato-vines, having at that time recently come out of the ground, where they pass the winter in the pupa state. They eat the leaves of the potato, gnawing irregular holes through them; and in the course of a few days begin to lay their oblong oval golden yellow eggs, which are glued to the leaves, in parcels of six or eight together. The grubs, which are hatched in about a fortnight afterwards, are of a dirty yellowish or ashen white colour, with a darker coloured head, and two dark spots on the top of the first ring. They are rather short, approaching to a cylindrical form, but thickest in the middle, and have six legs, arranged in pairs beneath the three first rings. After making a hearty meal upon the leaves of the potato, they cover themselves with their own filth. The vent is situated on the upper side of the last ring, so that their dung falls upon their backs, and, by motions of the body made for this purpose, is pushed forwards, as fast as it accumulates, towards the head, until the whole of the back is entirely coated with it. This covering shelters their soft and tender bodies from the heat of the sun, and probably serves to secure them from the attacks of their enemies. When it becomes too heavy or too dry, it is thrown off, but replaced again by a fresh coat in the course of a few hours. In eating, the grubs move backwards, never devouring the portion of the leaf immediately before the head, but that which lies under it. Their numbers are sometimes very great, and the leaves are then covered and nearly consumed by these filthy insects. When about fifteen days old they throw off their loads, creep down the plant, and bury themselves in the ground. Here each one forms for itself a little cell of earth cemented and varnished within by a gummy fluid discharged from its mouth, and when this is done it changes to a pupa. In about a fortnight more the insect throws off its pupa skin, breaks open its earthen cell, and crawls out of the ground. The beetles come out towards the end of July or early in August, and lay their eggs for a second brood of grubs. The latter come to their growth and go into the ground in the autumn, and remain there in the pupa form during the winter.

CROCODILE. A Saurian reptile of the first magnitude, and celebrated from the remotest antiquity for its terror-striking aspect and destructive power. We of course now allude to the species which inhabits the Nile and other large rivers of Africa; but as we have given the general character and habits of Crocodiles under the head "ALLIGATOR," the species peculiar to the American continent, that account should be referred to, and read in connection with what follows:—Crocodiles, like the rest of the Lacertæ, are oviparous: they deposit their eggs in the sand or mud near or on the banks of the rivers they frequent, and the young,

when hatched, immediately proceed to the water; but the major part are said to be generally devoured by other animals, as ichneumons, birds, &c. The egg of the common or Nilotic Crocodile is not much larger than that of a goose, but its form is more oblong. When the young are first excluded, the head bears a much larger proportion to the body than when full grown. The Crocodile preys chiefly on fish, but occasionally seizes almost on every animal which happens to be exposed to its rapacity; it is frequently met with twenty feet long, and the armour with which the upper part of the body is covered may be reckoned among the most elaborate specimens of Nature's mechanism. In the full-grown animal it is so strong and thick as easily to repel a musket ball; on the lower parts it is much thinner, and of a more pliable nature; and the whole appears as if covered with the most regular and curious carved-work. The colour of a full-grown Crocodile is blackish-brown above, and yellowish-white beneath; the upper parts of the legs and the sides varied with deep yellow, and in some parts tinged with green: in the younger ones the colour on the upper parts is a mixture of brown and pale yellow, the under parts being nearly white. The eyes are provided with a nictitating membrane, or transparent movable pellicle, as in birds; the mouth is of a vast width, the *vicus* or gape having a somewhat flexuous outline, and both jaws being furnished with very numerous sharp-pointed teeth, of which those about the middle part of each jaw considerably exceed the rest in size, and seem analogous to the canine teeth in the viviparous quadrupeds or mammalia. The tongue is attached by its entire marginal circumference to the lower jaw, and is not extensible, as in all true lizards: the ears are externally closed by two fleshy slips; the nostrils form a long narrow channel, which only opens anteriorly at the back of the throat; and under the throat there are two small pouches, which secrete a strong musky substance. The tail is long, powerful, of a laterally compressed form, and furnished above with an upright process, formed by the gradual approximation of two elevated crests proceeding from the lower part of the back: it accordingly serves as the principal means of propelling the body through the water when in pursuit of fish. The legs are very short, but strong and muscular: the hind feet have only four toes, which are united towards their base by a strong web: the two interior toes on each of the fore-feet, and the interior one on the hind feet, are destitute of claws.

There are also numerous other particulars connected with the anatomy of these beings, which are very curious and interesting. Such are the articulations of the lower jaw with the upper, the joint being so far back as to cause almost every incidental observer to believe that the upper, not the lower, jaw is moved in opening the mouth: the lateral spines on the vertebrae, which prevent the turning of the body, except in a large circle; the curious set of ribs designed exclusively for the protection of the belly, aided by two

broad bones standing on the anterior edge of the pelvis; the construction of the external ears; the apparatus for the protection of the eye, &c. &c.

The Crocodile of Egypt is no longer found except in the upper parts of that country, where the heat is greatest, and the population least numerous. Anciently, the species was common nearly to the outlet of the Nile; and it is stated by Pliny, that they used to pass the winter months buried in the mud, or in a state of torpidity. They are still common enough in the river Senegal, Jaire, &c. It is stated by excellent authorities, that they have occasionally been killed in Upper Egypt measuring thirty feet in length; and a very little reflection upon the muscular power of such a reptile will serve to convince us of its ability to commit the most dreadful ravages on the lives of other creatures. Were not such huge and ferocious animals rendered unwieldy by the length of the body and tail, they might become as dreadful on land as in the water; but when on shore, the difficulty they have in turning or of advancing otherwise than directly forward, enables men and animals readily to escape. In the water, the vast force it can exert by means of the long oar-like tail, amply compensates for want of flexibility, and renders the creature more than a match for any of its enemies. Crocodiles are exclusively carnivorous, and they always prefer their food in a certain state of putrefaction. It may be proper to add, that the Crocodile is supposed to be the *Leviathan* of the Scriptures: few persons, indeed, can have read the book of Job without being struck with the magnificent and terrible description of the attributes of Leviathan, to which alone the characters of the Crocodile correspond. [See GAVIAL, and ALLIGATOR.]

CROPPER. A particular species of Pigeon, which receives its name from a large crop under its beak, which it can either raise or depress at pleasure. [See PIGEON.]

CROSSBILL. (*Loxia*.) A genus of Passerine birds, the distinguishing characters of which are—that the tongue is plain, equal, and whole; and that the beak is large, thick,

CROSSBILL.—(*LOXIA CURVIROSTRA*.)

short, crooked, and convex both ways. This singular structure of the beak was considered

as a mere *usus naturæ* by Buffon; but, notwithstanding the apparently awkward and useless shape, it is found to be most admirably adapted to their particular habits. The two mandibles, instead of lying in a straight direction, cross each other in a similar manner to a pair of scissors, and which enables them to obtain their food with the greatest facility. They live mostly on the seeds of the cones of the fir; in procuring which they exhibit wonderful instinct, as they fix themselves across the cone, then bring the points of their beak immediately over each other, and insinuate them between the scales, which forcing them laterally, the scales open; and then again bringing the points in contact, they pick out the seed with the utmost ease.

The male of the COMMON CROSSBILL (*Loxia curvirostra*) varies from a beautiful red to orange colour on the head, neck, breast, back, and rump; the wing-coverts rufous brown; quills and tail dusky; tail forked; legs short; claws strong. The female in general is of a dull olive-green on those parts that are red in the male; wings and tail similar to the male, but not so dark. This species inhabits Sweden, Germany, and many other parts of Europe, where it breeds and migrates occasionally in vast flocks into the other parts: it is never known to breed in this country, but sometimes appears in immense numbers, fixing on those spots that abound with firs, for the sake of the seeds, which are its natural food. It is said to do a deal of mischief to orchards by splitting the apples to get at the seeds; and it is so intent when feeding on the cones of the firs (which it holds in its claws like a parrot), that it may be taken without difficulty. In North America and Greenland this bird is very common, and is said to build its nest in the highest parts of the firs, making use of the resinous matter that exudes from them for fixing it to the trees. It is sometimes called the German Parrot.

Another species, called the WHITE-WINGED CROSSBILL (*Loxia leucoptera*), which is somewhat less than a goldfinch, is common in North America. It is said to make its appearance in March, and to build its nest of mud and feathers in May, about half-way up a pine-tree, laying five white eggs speckled with yellow: in November both the old and young disappear, and are supposed to retire farther inland.

CROTALUS. [See RATTLESNAKE.]

CROTOPHAGA, or ANI. A genus of Scansorial birds found in the New World. The *Crotophaga Americana*, or Keel-bill, is principally an inhabitant of the hotter regions of South America, particularly Brazil, though it is met with also in North America, as well as in several of the West India islands. The general colour of these birds is black, with more or less of metallic reflections; and they have a short, arched bill, very much compressed. They live in flocks; the skirts of woods and the borders of flooded savannahs being their favourite haunts; and their food chiefly consisting of small lizards, insects and seeds. Their wings are short, and their flight feeble; but they are so bold and fear-

less as scarcely to be alarmed at the sound of fire-arms; and as they are not reckoned among edible birds, on account of the rank-

KEEL-BILL. — (*CROTOPHAGA ANI*)

ness of their flesh, they may be said to enjoy a kind of privileged security. Many pairs are said to use the same nest, which is built on the branches of trees, and of a large size; there they lay and hatch in concert. They are observed to breed several times in a year, and their eggs are of a bluish-green colour.

CROW. (*Corvus*.) Under the term *Corvidæ* will be found a brief account of the general characteristics of this gregarious and predatory genus of birds, of which the Raven may be considered the head. We are now about to speak of the COMMON or CARRION CROW (*Corvus corone*), which in form, colour, and appetites, so much resembles it.

The Carrion Crow is similar to the Raven in its habits, colour, and external appearance: length about eighteen inches; breadth three feet. The glossy feathers of the upper plumage have a burnished look, excepting on their edges, which are dull, and form a border to each. They live mostly in woods; build their nests in trees; and lay five or six eggs. They feed on putrid flesh, and garbage of all sorts; likewise on eggs, shell-fish, worms, and insects.

England is said to produce more birds of this kind than any other country of Europe. In the reign of Henry VIII. they were so numerous, and deemed so injurious to the farmer, that they were regarded as an evil worthy of parliamentary redress; and an act was accordingly passed for their destruction, in which rooks and choughs were included. Every hamlet was to provide crowns for ten years: and, during that space, the inhabitants were obliged to assemble at certain times, in order to project the most effectual methods for extirpating them.

The habits of this bird are so amusingly portrayed by Mr. Waterton, that we deem it no trespass upon the patience of our readers to quote his observations at considerable length. "This warrior bird," says he, "is always held up to public execration. The very word carrion, attached to his name,

carries something disgusting with it, and no one ever shows him any kindness. Though he certainly has his vices, still he has his virtues too; and it would be a pity if the general odium to which he is held should be the means, one day or other, of blotting out his name from the page of our British ornithology. With great propriety he might be styled the lesser raven in our catalogue of native birds; for, to all appearance, he is a raven; and I should wish to see his name changed, were I not devoutly attached to the nomenclature established by the wisdom of our ancestors.

"The Carrion Crow is a very early riser; and, long before the rook is on the wing, you hear this bird announcing the approach of morn, with his loud hollow croaking, from the oak to which he had resorted the night before. He retires to rest later than the rook: indeed, as far as I have been able to observe his motions, I consider him the first bird on wing in the morning, and the last at night, of all our non-migrating diurnal British birds. When the genial voice of spring calls upon him for the continuation of his species, the Carrion Crow, which up to this period has been wary, shy, and cautious, now, all of a sudden, seems to lose these qualities; and, regardless of personal danger, sometimes makes his nest within a hundred yards of the habitation of man, upon a tree, at once the most conspicuous and exposed. To us, who know so little of the economy of birds, this seems a strange phenomenon; nor can any penetration of which we may be possessed enable us to comprehend the true meaning of this change from timidity to boldness, from distance to proximity, from wariness to heedlessness, in so many different species of birds. One would suppose that they would be more shy and distant at this interesting period; and, in imitation of the cat, the rabbit, and the fox, conceal as much as possible the place of their retirement. The rook will sometimes build a poor and slovenly nest, but this is never the case with the Carrion Crow; this bird invariably makes its nest firm and compact; it never builds it in hedges, but will construct it in any of our forest trees; and, with me, it seems to give the preference, in general, to the oak, the spruce fir, and the Scotch pine. The young are hatched naked and blind, and remain blind for some days.

"Our ancestors, no doubt, bestowed the epithet *carrion* upon this bird, in order to make a clear and decided distinction between it (whose flesh they probably supposed was rank and bad) and the rook, the flesh of which was well known to be good and wholesome food. Perhaps, too, in those days of plenty, and of less trade, the Carrion Crow had more opportunities of tasting flesh than it has in these our enviable times of divers kinds of improvement. Were a Carrion Crow of the present day to depend upon the finding of a dead cow or horse for its dinner, it would soon become an adept in the art of fasting by actual experiment; for no sooner is one of these animals, in our neighbourhood, struck by the band of death, than its hide is sent to the tan-pit, and its remains are either

made into soup for the hunt, or carefully buried in the dunghill, to increase the farmer's tillage. The poor Crow, in the mean time, despised and persecuted for having an inclination to feed upon that of which, by-the-by, the occupier of the soil takes good care that he shall scarcely have a transient view, is obliged to look out for other kinds of food. Hence you see it regularly examining the meadows, the pastures, and the corn-fields, with an assiduity not even surpassed by that of the rook itself.

"The Carrion Crow will feed voraciously on ripe cherries; and, in the autumn, he will be seen in the walnut-trees, carrying off from time to time, a few of the nuts. With the exception of these two petty acts of depredation, he does very little injury to man during nine or ten months of the year; and if, in this period, he is to be called over the coals for occasionally throttling an unprotected leveret or a stray partridge, he may fairly meet the accusation by a set-off in his account of millions of noxious insects destroyed by him. However, in the spring of the year, when he has a nest full of young to provide for, and when those young begin to give him broad hints that their stomachs would like something of a more solid and substantial nature than mere worms and caterpillars, his attention to game and poultry is enough to alarm the stoutest-hearted squire and housewife. These personages have long sworn an eternal enmity to him; and he, in his turn, visits, to their sorrow, the rising hopes of the manor with ominous aspect; and he assaults the broods of the duck-pond, in revenge, as it were, for the many attempts which both squire and housewife have made to rob and strangle him.

"In 1815, I fully satisfied myself of his inordinate partiality for young aquatic poultry. The cook had in her custody a brood of ten ducklings, which had been batched about a fortnight. Unobserved by any body, I put the old duck and her young ones in a pond, nearly 300 yards from a high fir-tree in which a Carrion Crow had built its nest: it contained five young ones almost fledged. I took my station on the bridge, about 100 yards from the tree. Nine times the parent crows flew to the pond, and brought back a duckling each time to their young. I saved a tenth victim by timely interference. When a young brood is attacked by an enemy, the old duck does nothing to defend it. In lieu of putting herself betwixt it and danger, as the dunghill fowl would do, she opens her mouth, and shoots obliquely through the water, beating it with her wings. During these useless movements the invader secures his prey with impunity.

"Let us now examine if the attacks of this bird on domestic poultry cannot be easily counteracted; and whether its assiduous attention to the nests of pheasants and of partridges is of so alarming and so important a nature as to call for its utter extermination from the land. For my own part, I acknowledge that I should lament his final absence from our meadows and our woods.

His loud and varied notes at early dawn, and again at latest eve, are extremely grateful to me; and many an hour of delight do I experience, when, having mounted up to the top of a favourite aged oak which grows on the border of a swamp, I see him chasing the heron and the woodhoop through the liquid void, till they are lost in the distance. Then, again, how eager is his pursuit!—how loud his croaking!—how inveterate his hostility!—when he has espied a fox stealing away from the hounds, under the covert of some friendly hedge. His compact and well-built figure, too, and the fine jet black of his plumage, are, in my eye, beautifully ornamental to the surrounding sylvan scenery."

The HOONEN CROW (*Cervus cornix*) is a bird of passage, which visits England in the beginning of winter, and leaves it with the woodcock. It is found both in the inland and maritime parts of this kingdom; and, in the latter, it feeds on crabs and other shellfish. It is very common in many parts of the Highlands of Scotland, the Hebrides, Orkneys, &c. They build indifferently in all kinds of trees; lay six eggs; have a shriller voice than the common Crow; and are much more mischievous.

CROW SHRIKE. (*Cracticus*.) A genus of birds found in Madagascar, New Holland, &c., of which there are several species.—The BLACK-THROATEN CROW SHRIKE (*Cracticus nigrogularis*, Gould) is a handsome species, with a black head, neck, and breast; the under parts, the hinder part of the neck,

CROW SHRIKE
(*CRACTICUS NIGROGULARIS*.)

shoulders, centre of the wing, white; the tail black, the ends of the feathers white, except the two middle feathers, which are black. It is a native of New South Wales, is usually seen in pairs, and from its active habits and conspicuous pied plumage, forms a striking object among the trees. It feeds on insects and small lizards, but is not satisfied with such trifling prey; its powerful and strongly hooked bill makes it a formidable enemy to young birds, mice, and other small animals, which it soon kills, tears to pieces, and devours on the spot. Mr. Gould, in his invaluable work on the "Birds of Australia," from which our figure is copied, tells us that wounded individuals on being handled inflict severe blows. The nest is like that of a jay.

CRUSTACEA, or CRUSTACEANS. The term applied to those animals which are covered with a soft shell or crust. These consist of crabs, lobsters, and many others of

a much less complicated structure, and of a different external form. They are called articulated animals—that is, those whose members or limbs consist of segments or rings, articulated into each other, to the inside of which their muscles are attached. The tegumentary skeleton of Crustacea generally possesses a considerable degree of stony hardness; and, indeed, contains no small proportion of carbonate of lime. This solid envelope may be looked upon as a kind of epidermis; for beneath it we find a membrane like the true skin of higher animals; and at certain times it detaches itself and falls off, in the same manner as the epidermis of reptiles separates itself from their bodies. The way in which they free themselves from their old shell is exceedingly singular. In general, they manage to get out of it without occasioning the least change in its form. When they are first denuded, the whole surface of their bodies is extremely soft, and it is not for some time that the substance which has been exuded from the pores on the surface of their skin, acquires a hard consistence.

Crustaceous animals present remarkable physiological distinctions. They respire by means of *branchia*, or branchial plates, usually attached to their feet or to their jaws; they have from five to seven pairs of feet; their head is frequently not distinct from the trunk, provided with from two to four jointed, setaceous antennae; and two compound movable eyes seated on peduncles, which are sometimes movable, and at others fixed: they have a distinct heart, and a regular circulating system: and their organs of reproduction are placed either in the feet or tail. In those genera where the head is not separated from the trunk, the shield or covering envelopes the whole thorax. In other genera the head is distinct from the body, which is divided into seven segments, to the lower sides of which the feet are attached; these for the most part have a tail, consisting of many segments. The limbs vary from ten to fourteen, each having six articulations. The two anterior limbs, and sometimes even three on each side, are provided with forceps; at other times they are terminated by simple hooks, and in many instances by appendages which fit them for swimming. The mouth has usually two mandibles, a *labium* or lip below, and from three to five pairs of jaws: these small leg-shaped appendages are not fitted for locomotion, but, being situated near the mouth, assist in the operation of feeding.

Animals of this class live in various situations, suited to their organization: some inhabit considerable depths of the ocean, others are found on rocky shores, or in muddy shallows; some, such as crawfish, inhabit rivers, under stones and banks; while the land-crab takes up its abode in inland situations, making periodical journeys to the coast in vast numbers, for the purpose of depositing its eggs. [See CRAB.] Some of the Crustacea have the power of emitting light in the dark. Others are endowed with the power of not only detaching one of their limbs, when seized upon by an

enemy, but have also the faculty of reproducing the severed limb, which, however, is always of a less size than the others, until it has once or twice changed its crust.—The reader is referred to Prof. Milne Edwards's *Hist. Nat. des Crustacées*, and to Prof. Bell's *British Crustacea*, for further information. See also numerous scattered articles in this work.

CRUSIAN. (*Cyprinus curassius*.) A fish of the carp kind, which, though common enough in many parts of England, is believed to be not a native fish. It is from eight to ten inches in length; very deep and thick, and the back much arched. The colour is a deep olivaceous yellow, with a slight silvery tinge on the belly; lateral line straight; fins dull violet; the dorsal fin broad, and extending a considerable distance from the middle of the back towards the tail. The flesh is coarse.

CTENOIDEA. [See SUPPLEMENT.]

CTENOMYS. [See TECTICO.]

CUCKOO. (*Cuculus canorus*.) This bird, whose parasitic habits have so long been a subject of popular interest, and regarding whose general economy so much speculation has been indulged in, is about fourteen inches in length, and twenty-five in breadth when extended: the bill is black and somewhat bent; irides yellow; inside of the mouth red; its head, neck, back, and wing-coverts pale blue, darkest on the head and back, and palest on the forepart of the neck and rump; breast and belly white, elegantly crossed with wavy bars of black; quill feathers dusky, the inner webs marked with white oval spots; the tail long, the two middle feathers black, with white spots on each side of the shaft; legs short and yellow; toes, two forward, two backward; the outer one being directed forward or backward at pleasure; claws white. The female is rather less than the male, and

CUCKOO.—(*CUCULUS CANORUS*.)

somewhat differs in colour; the neck and breast being of a tawny brown, with dusky bars; and the wing-coverts marked with light ferruginous spots. The plumage of the young is very dissimilar to that of the adult bird; it is supposed, indeed, that they

do not throw off the nestling feathers till the second year's moulting.

The Cuckoo is a migratory bird, visiting this country early in spring, and generally quitting it at the commencement of July: its well-known note is usually first heard about the middle of April, and ceases at the end of June. Contrary to the general economy of the feathered creation, it constructs no nest, and never hatches its own eggs; but deposits them in the nests of other birds, as the hedge-sparrow, titlark, water-wag-tail, &c., preferring, as it would seem, the first-mentioned. During the time the hedge-sparrow is laying her eggs, which generally occupies four or five days, the Cuckoo contrives to deposit her egg among the rest, leaving the future care of it entirely to the hedge-sparrow. This intrusion often occasions discomposure, for the hedge-sparrow, at intervals, whilst sitting, not only throws out some of her own eggs, but injures others in such a way that they become addled, so that not more than two or three of them are hatched along with that of the Cuckoo; and what is very remarkable, she never throws out or injures the egg of the intruder. When she has disengaged the young Cuckoo and her own offspring from the shell, her young ones, and any of the eggs that remain unhatched, are soon turned out by the young Cuckoo, who then remains in full possession of the nest, and becomes the sole object of the care of its foster parents. The young birds are not previously killed, nor the eggs demolished, but all are left to perish together, either entangled in the bush which contains the nest, or lying on the ground near it. The mode of accomplishing the ejectment is curious: The Cuckoo, very soon after being hatched, and consequently while it is yet blind, contrives with its rump and wings to get the hedge-sparrow, or the egg, upon its back, and making a lodgment for its burden by elevating its elbows, clambers backwards with it up the side of the nest, till it reaches the top, where, resting for a moment, it throws off its load with a jerk, and quite disengages it from the nest; after remaining a short time in this situation, and feeling about with the extremities of its wings, as if to be convinced that the business has been properly executed, it drops into the nest again. Nature seems to have provided, even in the formation of the Cuckoo, for the exercise of this peculiar instinct; for, unlike other newly hatched birds, its back, from the scapulae downwards, is very broad, with a considerable depression in the middle, as if for the purpose of giving a more secure lodgment to the egg, or the young bird, while the intruder is employed in removing either of them from the nest; when about twelve days old, this cavity is filled up, the back assumes the shape of nestling birds in general, and the disposition for turning out any bird or substance placed in the nest entirely ceases. The smallness of the Cuckoo's egg is another circumstance deserving attention in this surprising transaction; in size and appearance it differs little from the egg of the Skylark and Titlark, though the disparity of the bulk of the

birds is very great: in short, everything conspires, as might be expected, to render perfect the design which is to be accomplished by the seemingly unnatural propensity of this bird.

The growth of the young Cuckoo is extremely rapid: it has a plaintive chirp which is not learned from its foster-parent; and it never acquires the adult state during its stay here. A fierceness of disposition shows itself long before it leaves the nest; for when irritated it assumes the manners of a bird of prey, often making a chuckling noise like a young hawk. When it is sufficiently fledged, it does not long remain the inmate of its supposed parent's domicile; for as its appetites for insect-food increase, it cannot expect to obtain a supply by imitating its little instructor: it therefore takes a final leave of, and seldom offers any violence to, its nurse. All the little birds, however, who consider the young Cuckoo as their enemy, show an inclination to revenge the general cause, and compose the train of its pursuers; but none of them are so active in the chase as the Wryneck, who, from this circumstance, has been erroneously considered by many as the Cuckoo's attendant and provider. The Cuckoo is said to be a fierce pugnacious bird. Its principal food consists of hairy caterpillars, grasshoppers, snails, moths, cockchafer, &c., of which it disgorges the hard parts after digestion, in the same manner as birds of prey: it is also said to eat the eggs of other birds. Mr. White (of Selborne) remarks, however, that Cuckoos cannot be birds of prey, as they have a weak bill and no talons.

Although we have already extended this article to a greater length than was our intention, we cannot refrain from making room for the following remarks by Mr. Jesse:—"There is still a great mystery attached to the natural history of the Cuckoo, and one would willingly, if possible, rescue it from the charge of a want of that natural affection which has been alleged against it. It has been stated that what has been said by a very ancient and sublime writer, concerning the defect of natural affection in the ostrich, may be applied to the Cuckoo. It is now, however, pretty well ascertained that the ostrich only quits her eggs when the sun is so powerful that the additional warmth from her body would be detrimental to them. She therefore returns to them in the cool of the evening. I am persuaded that the more we inquire and search into the economy of nature, so far from finding any defects, we shall have more and more reason to be convinced that not only every bird, but every animal from the highest to the lowest in the scale of creation, is equally well adapted for the purpose for which it was intended." We should have mentioned that it is to Dr. Edward Jenner, who first introduced vaccination, that we are indebted for having given the earliest and fullest account of the habits of this singular bird. Many of our readers are doubtless familiar with Logan's fine address to the Cuckoo, beginning,

"Hail! beautiful stranger of the grove!"

THE GREAT SPOTTED CUCKOO. (*Oxylophus glandarius*.) This species inhabits both the south and the north of Europe; and is about the size of a Magpie. The beak is black, and a little bent; head crested; the crest being composed of bluish ash-coloured feathers; from the base of the upper mandible arises a band of black, which passes through the eyes almost to the hinder part of the head, and is broadest in the middle: scapulars, upper wing, and tail-coverts, dark brown, marked with small white and pale cinereous spots; quill-feathers brown; tail wedge-shaped, blackish, and all tipped with white except the two middle feathers: legs and claws black.

THE ORIENTAL CUCKOO. (*Eudynamis Orientalis*.) There are several varieties of this species. The first is the size of a pigeon: length about sixteen inches; beak grey-brown; plumage nearly black, with a green gloss, which in some parts assumes a sort of violet hue. The tail is eight inches long; the legs are of a dusky grey colour; claws black: it is found in the East Indies.—The next variety inhabits Mindanao: it is fourteen inches long; beak black, yellow at the tip; the plumage a blue-black; and the tail generally carried spread.—A third variety is about nine inches in length: beak bright orange; plumage black, glossed with green and violet; tail wedge-shaped; legs reddish-brown; claws nearly black. This species frequents woods, and for the most part flies in small flocks. It is held in veneration by the Mahometans; but by epicures, who have no religious prejudices in its favour, it is esteemed a great delicacy.

THE GILDED CUCKOO. (*Chrysococcyx auratus*.) This beautiful little specimen of the Cuckoo tribe is about seven inches in length: the beak is of a greenish brown colour; and the upper parts of the body are of a rich gilded glossy green; on the head are five stripes of white; nearly all the wing-coverts and the second quills have white tips, as likewise the tail-feathers and the two greater tail-coverts; the throat and breast white; the sides and feathers which fall over the knees marked with a few greenish bars; legs grey, covered with white feathers as far as the middle: tail wedge-shaped, above three inches long, and in its natural state spread out like a fan. Le Vaillant, who discovered this species in Southern Africa, remarks that it is undoubtedly the finest bird of the genus.

There are many genera and species of Cuckoos, it being a very extensive family; and a fine collection of them is to be seen in the British Museum. We find it necessary, however, to give but one more, and that is—

THE YELLOW-BILLED AMERICAN CUCKOO (*Coccyzus Americanus*), the description of which we take from Wilson, as follows:—"From the imitative sound of its note, it is known in many parts by the name of the *cow-bird*; it is also called in Virginia the *rain-crow*, being observed to be most clamorous immediately before rain. This species arrives in Pennsylvania, from the south,

about the 22nd of April, and spreads over the country, as far at least as Lake Ontario; is numerous in the Chickasaw and Chactau nations; and also breeds in the upper parts of Georgia; preferring, in all these places, the borders of solitary swamps, and apple orchards. It leaves us, on its return southward, about the middle of September.

"The singular, I will not say unnatural, conduct of the European Cuckoo (*Cuculus canorus*), which never constructs a nest for itself, but drops its eggs in those of other birds, and abandons them to their mercy and management, is so universally known, and so proverbial, that the whole tribe of Cuckoos have, by some inconsiderate people, been stigmatized as destitute of all parental care and affection. Without attempting to account for this remarkable habit of the European species, far less to consider as an error what the wisdom of Heaven has imposed as a duty upon the species, I will only remark, that the bird now before us builds its own nest, hatches its own eggs, and rears its own young; and, in conjugal and parental affection, seems nowise behind any of its neighbours of the grove.

"Early in May they begin to pair, when obstinate battles take place among the males. About the 10th of that month they commence building. The nest is usually fixed among the horizontal branches of an apple-tree; sometimes in a solitary thorn, crab, or cedar, in some retired part of the woods. It is constructed, with little art, and scarcely any concavity, of small sticks and twigs, intermixed with green weeds and blossoms of the common maple. On this almost flat bed, the eggs, usually three or four in number, are placed; these are of a uniform greenish blue colour, and of a size proportionable to that of the bird. While the female is sitting, the male is generally not far distant, and gives the alarm, by his notes, when any person is approaching. The female sits so close, that you may almost reach her with your hand, and then precipitates herself to the ground, feigning lameness, to draw you away from the spot, fluttering, trailing her wings, and tumbling over, in the manner of the partridge, woodcock, and many other species. Both parents unite in providing food for the young. This consists, for the most part, of caterpillars, particularly such as infest apple-trees. The same insects constitute the chief part of their own sustenance. They are accused, and with some justice, of sucking the eggs of other birds, like the crow, the blue jay, and other pillagers. They also occasionally eat various kinds of berries. But, from the circumstance of destroying such numbers of very noxious larvae, they prove themselves the friends of the farmer, and are highly deserving of his protection.

"The Yellow-billed Cuckoo is thirteen inches long, and sixteen inches in extent; the whole upper parts are of a dark glossy drab, or what is usually called a Quaker colour, with greenish silky reflections; from this must, however, be excepted the inner vanes of the wings, which are bright reddish cinnamon; the tail is long, composed of ten

feathers, the two middle ones being of the same colour as the back, the others, which gradually shorten to the exterior ones, are black, largely tipped with white; the two outer ones are scarcely half the length of the middle ones. The whole lower parts are pure white; the feathers covering the thighs being large, like those of the hawk tribe. The legs and feet are light blue, the toes placed two before and two behind, as in the rest of the genus; the bill is long, a little bent, very broad at the base, dusky black above, and yellow below; the eye hazel, feathered close to the eyelid, which is yellow. The female differs little from the male; the four middle tail-feathers in her are of the same uniform drab; and the white, with which the others are tipped, not so pure as in the male. In examining this bird by dissection, the inner membrane of the gizzard, which in many other species is so hard and muscular, in this is extremely lax and soft, capable of great distension; and, what is remarkable, is covered with a growth of fine down, or hair, of a light fawn colour." A specimen of this bird is said to have been found in this country.

CUCKOO-SFIT. [See CERCOPIDÆ.]

CUCULIDÆ. An extensive family of Passerine birds, characterized by having the toes situated two before and two behind; and so named from including as the typical species the well-known Cuckoo. These birds are for the most part inhabitants of the warm climates, and none permanently reside in countries subject to severe winter cold. They have a slightly arched compressed beak, and a long rounded tail; their wings are moderately long, and they fly with rapidity. They feed on insects, worms, and soft fruits, which they procure while leaping from branch to branch, or sitting from tree to tree: when on the ground they walk awkwardly, on account of the shortness of their tarsi. [See CUCKOO.]

CUCULINÆ. The name given to denote that sub-family of the CUCULIDÆ which consists of the genuine Cuckoos.

CULEX: CULICIDÆ. A genus and family of Dipterous or two-winged insects, consisting of the various kinds of Gnats. They are distinguished by the length of the proboscis, and their beautifully tufted antennæ. They generally abound in damp situations, their larvae being inhabitants of the water. [See GNAT: MOSQUITO.]

CURASSOW. (*Craz.*) A genus of Gallinaceous birds, inhabiting various parts of South America. They are nearly as large as a turkey.

The CRESTED CURASSOW. (*Craz alector.*) This bird is nearly three feet in length. The crest, which it can elevate or depress at pleasure, is composed of twisted black feathers, narrow at the base and broad at the tip: the whole of the upper part of the plumage is of a deep shining black colour, reflecting purple and green shades; the tail is black, generally tipped with white; the abdomen and the inferior tail-coverts are

invariably white. The females have a smaller crest, and their feathers are more dull.

CRESTED CURASSOW. (*Crax alpektor*.)

They associate in small flocks, and at night roost on high trees: their food consists of maize, rice, bananas, and other fruits. The egg is about the size of that of the turkey, and is of a pure white. Native of Guiana, Mexico, and Brazil.

The RED CURASSOW. (*Crax rubra*.) In size this bird may be compared with the turkey, being about two feet six or eight inches in length. It has a large, strong bill; and a crest composed of twisted and curled feathers, broad at the top, and tipped with black: the front and sides of the head, and the top of the neck, are pure white, the feathers being marked at their tips with a black fringe: the breast and the upper parts of the tail are reddish, the under parts a brighter red than the upper: the feet and the bill are of horn colour. The young of this species are beautifully varied: the sides of the head and top of the neck are barred with black and white; the upper part of the plumage, as well as the tail-feathers, are striated with broad, transverse, red and white bands, margined with a black line: as the bird increases in age these bands gradually disappear, and the feathers of the crest, which are at first straight, begin to twist and curl. In their native country these birds are easily tamed, and readily associate with other poultry; but although they are here common enough in menageries, they have never been known to breed. Temminck, however, says, they have once at least been thoroughly acclimated in Holland, where they were as prolific in their domesticated state as any of our common poultry: and Mr. Bennet, alluding to the same subject, observes, "It may not be too much to expect that the Zoological Society may be successful in perfecting what was then so well begun, and in naturalizing the Curassow as completely as our ancestors have done the equally exotic, and, in their wild state, much less familiar breeds of the Turkey, the Guinea-fowl, and the Peacock." Their flesh is both delicate and nutritious.

CURCULIO: CURCULIONIDÆ. A genus and family of snouted Coleopterons or insects, including the diamond beetles and other splendidly coloured species; as well as the corn and nut weevils, and a variety of others scarcely less destructive to grain, fruit, and vegetable products in general; several of

which are given under their respective names. M. Schönlerr has published a voluminous work which describes the numerous species. Mr. Walton, F. L. S., has studied the British *Curculionide*, and published excellent papers on all the species found in this country.

CURLEW. (*Numenius*.) A Grallatorial bird, belonging to the *Scolopacidae*, or Snipe tribe, all of which inhabit the vicinity of waters and marshes, and feed upon worms, &c. The COMMON CURLEW (*Numenius arquata*) measures about two feet in length; and in breadth, from tip to tip, above three feet. The bill is about seven inches long, of a regular curve, and blunt at the end: the upper mandible is black, gradually softening into brown towards the base; the under one flesh-coloured. The head, neck, and wing-coverts are streaked with brown; the back and scapulars are nearly black in the middle, edged and deeply indented with light grey. The breast, belly, and lower part of the back are of a dull white, spotted with black; the quill-feathers are black, the inner webs crossed with white: tail barred with black, on a white ground tinged with red: thighs bare about half way above the knees, of a bluish-colour: the toes are thick, and slightly membranous. The female makes her nest upon the ground, in a dry tuft of rushes or grass; and lays four eggs of a greenish cast, spotted with brown.

The Curlew is met with in most parts of Europe. In Britain their summer haunts are the large, heathy, and boggy moors, where they breed; their food consisting of worms, flies, and insects, which they pick out of the soft mossy ground by the marshy pools. In autumn and winter they depart to the sea-side in great numbers, and there subsist upon worms, marine insects, small crabs, snails, &c. This bird is extremely common in most parts of Europe, and it occurs also in several parts of Asia. In the winter it is gregarious, and it is at all times very shy and difficult to approach; but it will soon become familiar. In Scotland, from its cry it is called the "Whaup." [For another species, see WHIMBREL.]

CURSURIUS. This genus of birds inhabits the hot regions of Asia and Africa; one species only, and that very rarely, having been found to visit Europe. The CREAM-COLOURED CURSURIUS (named by Temminck *Cursorius Isabellinus*) is ten inches in length; and has a black, curved beak; the forehead, under parts of the body, back, tail, and wing-coverts of a reddish cream-colour; the latter edged with grey: behind the eyes a double black stripe; the throat and belly whitish; the whole of the lateral tail-feathers black towards the tip, with a small spot of white in the centre of the black: legs yellowish. This rare species is a native of Africa; but with its habits we are unacquainted. Two only are on record as seen in England: one which was shot near St. Albans, in East Kent, the seat of W. Hammond, Esq., Nov. 10. 1785; and another, shot in Chamwood Forest, Leicestershire, Oct. 15. 1827. The former of these was observed to run with incredible swift-

ness, and at intervals to pick up something from the ground; and was so bold as to render it difficult to make it rise from the ground, in order to take a more secure aim on the wing. The note was unlike that of any known bird. A British-killed specimen of this desert-loving bird is preserved in the fine collection in the British Museum.

CURUCUI. [See **TROGON**.]

CURVIROSTRA. [See **CROSSBILL**.]

CUSIAT. The Wood-pigeon [which see].

CUTTLE-FISH. (*Octopus*.) A molluscous animal, belonging to the genus *Sepia*, order *Cephalopoda*; and sometimes called the Ink-fish. It is of an oblong form, about six inches in length, and three and a half in breadth. The body is somewhat oval; but it is broadest near the head, and grows smaller towards the extremity, where it is obtusely pointed. The head is surrounded with eight arms and two feet; the two feet being nearly similar in their structure to the arms, or tentacula, but considerably larger in their dimensions. The head is divided from the sac on all sides by a neck. The sac is furnished on each side throughout its whole length with a narrow fin. The suckers are irregularly scattered on the arms

CUTTLE FISH. — (OCTOPUS)

and feet. The back is strengthened by a complicated calcareous plate, which plate has been long known in the shop of the apothecary under the name *Cuttle-fish bone*, and was formerly much prized in medicine as an absorbent, but is now chiefly sought after for the purpose of polishing the softer metals. The superior half, or the one next the head, is the longest, rounded at the extremity, and thin. The inferior portion becomes suddenly narrow, and ends in a point. It may be considered as consisting of a dermal plate, concave on the central aspect, having its concavity filled up with layers which are convex on their central aspect. The dermal plate consists of three different laminae, arranged parallel to one another. The external or dorsal lamina is rough on the surface, and marked by obscure, concentric arches towards the summit, formed by minute knobs, which become larger towards the base, where they appear in the form of interrupted trans-

verse ridges. It is uniform in its structure, and the tubercles possess a polish and hardness equal to porcellaneous shells, although they blacken speedily when put in the fire, and contain a good deal of animal matter. On the central side of this layer is one flexible and transparent, similar to horn, and smooth on the surface. The third layer is destitute of lustre; and, in hardness and structure, resembles mother-of-pearl shells. The term *bone* has been improperly applied to this complicated plate; for this substance, in composition, is exactly similar to shell, and consists of various membranes, hardened by carbonate of lime, without the smallest mixture of phosphate. Under the throat there is a vessel or bladder containing a fluid blacker than ink, which the Cuttle-fish, when pursued by its enemies, ejects in considerable quantities; and this, darkening the water all around, enables it to escape with facility. The most remarkable species of the genus is the *Sepia officinalis*, which is distinguished from the others by its smooth skin. It inhabits the British seas, and although seldom taken, its "bone" is cast ashore on different parts of the coast, from the south of England to the Zetland isles. It is said that the Cuttle-fish is considered a luxury by all classes of the Sandwich islanders, and that when fresh and well cooked it is excellent, being in consistence and flavour not unlike the flesh of a lobster's claw.

The singular habits of the Cuttle-fish did not escape the notice of Mr. C. Darwin, while at the Cape de Verd islands. "I was much interested," says he, "on several occasions, by watching the habits of an *Octopus* or Cuttle-fish. Although common in the pools of water left by the retiring tide, these animals were not easily caught. By means of their long arms and suckers, they could drag their bodies into very narrow crevices: and when thus fixed, it required great force to remove them. At other times they darted, tail first, with the rapidity of an arrow, from one side of the pool to the other, at the same instant discolouring the water with a dark chestnut-brown ink. These animals also escape detection by a very extraordinary, chameleon-like power of changing their colour" [which Mr. D. minutely describes]. He then adds: "I was much amused by the various arts to escape detection used by one individual, which seemed fully aware that I was watching it. Remaining for a time motionless, it would then stealthily advance an inch or two, like a cat after a mouse; sometimes changing its colour: it thus proceeded, till, having gained a deeper part, it darted away, leaving a dusky train of ink to hide the hole into which it had crawled. . . . That it possesses the power of ejecting water there is no doubt, and it appeared to me certain that it could, moreover, take good aim by directing the tube or siphon on the under side of its body."

CYAMUS, or WHALE LOUSE. A small crustaceous animal belonging to the order *Lamodipoda*. This minute claw-limbed creature, with others allied to it, inhabits the seas of northern and temperate Europe,

WHALE LOUSE.
(CYAMUS CETI.)

are subject to parasitic, as well as many other enemies. [See WHALE.]

CYCLOIDEA. [See SUPPLEMENT.]

CYCLOPS. A genus of minute Crustaceans, comprising numerous species, some of which belong to fresh-water, while others are marine. The fresh-water species abound in the muddiest and most stagnant pools, and often too in the clearest springs: the marine species are to be found, often in vast numbers, among the sea-weeds, in small pools on the sea-shore; others there are which inhabit the open ocean, where, by the luminous properties they possess, they contribute to its phosphorescence. They take their name from having but one eye. They have all eight or ten legs, and the abdomen is terminated by a hind tail adapted for swimming. Dr. B. has monographed the British species.

CYCLOPTERUS. [See LUMP-FISH.]

CYGNUS. [See SWAN.]

CYNIPS: CYNIPIDÆ. A genus and family of Hymenopterous insects, commonly known by the name of *Gall-flies*. These in-

GALL INSECT.—(CYNIPS QUERCUSFOLIA.)

sects puncture, with their ovipositor, the surface of the leaves, buds, and stalks of various plants and trees; and they increase the aperture by means of the toothed edge, forming a kind of saw, with which the extremity of this organ is armed. In this aperture they deposit, with the egg, a drop of fluid, which, from its irritating quality, produces different kinds of gall-nuts, according to the species of *Cynips* by which it has been punctured.

The excrescences on the leaves and buds of trees which are called *Galls* are of various shapes: many are spherical; others are hairy or tomentose, the surface emitting numerous fibrous threads; others resemble buds, flowers, &c.; and there are a few which are flat: in most of the species a single gall supports only a single gall-insect; while others

are *polythalamous*, serving for the residence of many. "Probably," says Mr. Westwood, "no insect has been of greater benefit to mankind than the *Cynips Gallæ tinctoria*, the galls of which are the common gall-nuts of commerce, growing upon the *Quercus tinctoria* in the Levant, and which are employed in the manufacture of ink. The galls are of the size of a boy's marble, very hard and round, with various tubercles on the surface; they contain but a single inhabitant, which may often be found in the interior on breaking the galls. This species resembles some of our English species which reside in globular oak-galls in its habits of undergoing its transformations within the gall, leaving a great portion of the gall unconsumed. Those galls which are gathered before the insect has escaped (and which consequently contain most astringent matter) are known in trade under the name of black or blue galls and green galls; but those from which the insect has escaped are called white galls.

CYNTHIA. A genus of Diurnal Lepidoptera, belonging to the Nymphalidæ: we restrict ourselves to the mention of the British species.

CYNTHIA CARDUI; or **PAINTED LADY.** This species of Butterfly is noted for the irregularity of its appearance in particular districts. The wings in general

PAINTED LADY BUTTERFLY.
(CYNTHIA CARDUI.)

are of a brownish yellow colour, dappled with black spots or clouds of various shapes; especially those parts of the upper wings

UNDER SIDE OF PAINTED LADY BUTTERFLY. next the apices, which are all black, except five white spots on each side. On the under

side the superior wings are of a fine light orange-colour, but they become of a deep crimson near the body; and the parts towards the tips are of a pale brown, having five white spots, corresponding with those on the upper surface; the remaining parts are dappled with black, with one large white and nearly square spot on the sector edge. The inferior wings are of a pale yellow brown, dappled with dark brown spots nearly equal in size; and near the lower border are five ocelliform spots. The caterpillar, which feeds on thistles, nettles, mallows, &c., is a grayish brown, with yellow lateral lines. The chrysalis is grayish, with golden dots, and whitish brown longitudinal streaks.

"On the blue heads of the pasture scabious (*Scabiosa succisa*)," says the author of the Journal of a Naturalist, "we occasionally see, toward the end of the summer, the Painted Lady Butterfly (*Cynthia cardui*); but this is a creature that visits us at very uncertain periods, and is vivified by causes infinitely beyond the comprehension of the entomologist, seeming to require a succession and variety of seasons and their change, and then springing into life we know not how. This was particularly obvious in the summer of 1815, and the two following, which were almost unceasingly cold and rainy; scarcely a moth or butterfly appeared. And in the early part of 1818, the season was not less ungenial; a few half-animated creatures alone struggled into being; yet this "painted lady" was fostered into life, and became the commonest butterfly of the year: it has, however, but very partially visited us since that period. The keenest entomologists, perhaps, would not much lament the absence of this beauty, if such cheerless seasons were always requisite to bring it to perfection. Some years ago a quantity of earth was raised in cutting a canal in this country; and in the ensuing summer, on the herbage that sprang up from this new soil on the bank, this butterfly was found in abundance, where it had not been observed for many years before. In some particular seasons we have acres of this scabious in bloom, during the months of September and October, giving a tender shade of lavender colour to the whole field, affording now great pleasure to the entomologist, by reason of the multitude of insects that resort to it for the honey in the tubular florets in the plant. Late as this period is, I have seen, in some bright morning, besides multitudes of bees, flies, and such creatures, eleven different species of lepidopterous insects, feeding and balancing on the blue heads and glancing their gay wings in the sunny beam." This species is, apparently, found every where; and in the Museum collection are specimens from nearly every part of the world.

CYNOCEPHALUS. [See BARBOON.]

CYPHONIDÆ. A group of beetles detached from the *Cebrionidæ* on account of their small size; œnospheric, depressed, or ovate, and rather soft bodies, and furcate labial palpi: they are of dull colours, and attached to plants in damp situations; and

they fly and run with agility. In some species the hind legs are formed for leaping.

CYPRÆA. A genus of univalve shells, called also *Cowries*, remarkable for the brilliancy of their colours, and for the high polish of which they are susceptible. The animal they contain is a *Gastropodus* Mollusc; and the shell of one species, the *Cypræa moneta*, is well-known in commerce as the current coin of the natives of Siam, Bengal,

COWRIE. — (CYPRÆA STOLIDA.)

and many parts of Africa: in the latter it is collected by the female negroes, and is thence sent to distant countries. The *Cypræidæ*, or shells of the *Cypræa* genus, are generally semi-oval, having their mouths placed in their flat part; their spires are not externally visible, the revolutions being performed within the body of the shell; the aperture, or mouth, is a narrow opening, running the entire length of the shell; the lips, which are near each other, are broad, turning inwards, and serrated; and the two ends or extremes on the upper part are very prominent. At one end there appears a wry channel, or opening; the other end has also an opening, but placed perpendicularly. *Cypræidæ* abound both in the old and new world, but their greatest development both in point of size and number of species takes place in warm climates. In the Friendly Islands, permission to wear the *Cypræa aurantia*, or Orange Cowry, as an ornament, is only granted to persons of the highest rank. Mr. Gray, F.R.S., has published an admirable monograph of the Cowries; and the Messrs. Sowerby subsequently figured all the species. They are much prized by collectors.

CYPRINIDÆ. A family of Malacopterygious abdominal fishes, of which there are many genera, the principal being *Cyprinus carpio*, the common Carp. They are for the most part fresh-water fishes; live on

CARP. — (CYPRINUS CARPIO.)

aquatic plants; and are characterized by their small mouth, and by their feeble and generally toothless jaws. They have a scaly body, no adipose fin, a stomach destitute of a *cul de sac*, and no pyloric cæca. The different varieties of Gold and Silver Fish, the Gudgeon, Tench, Bream, Roach, Bleak, Minnow, and many other well-known pond and river fishes, belong to this family.

CYPRIS. A genus of Entomostracous Crustacea, containing numerous species, many of which are British. Their general appearance, to one ignorant of natural his-

CYPRIS VIRVA

tory, is that of a bivalve shell. They are mostly found in fresh or stagnant water, where they sometimes abound in myriads. Delicate though they are, yet there are abundant indications, in strata of different formations, of their existence in a previous condition of the world, and, like shells and some other fossils, they form curious and interesting medals of creation. [See ENTOMOSTRACA.]

CYPRUS BIRD. The Black-cap (*Sylvia atricapilla*), which has received this name from its frequency in the isle of Cyprus. It is by no means uncommon in this country. [See BLACK-CAP.]

CYTHAREA. A genus of marine Mollusca, of which there are numerous species, inhabiting the Indian and Atlantic Oceans. The shell is equivalve, inequilateral, triangular or transverse; ligament on the longest side; four cardinal teeth in one valve, and three in the other. In their beauty and colouring these shells much resemble the *Venus*. One species, the *Cytherea lusoria*, is found in the Chinese seas: it is used by the Japanese and Chinese in certain games, and the interior is painted by them of various colours.

DAB. (*Pleuronectes limanda*.) This species of flat-fish is of a very broad, ovate shape; generally of a uniform pale brown colour on the upper side, and white on the under side; the lateral line is very much curved at the beginning, but afterwards proceeds straight to the tail. It is usually caught along with Plaice and Flounder, from which it is readily distinguished by the roughness of its scaly surface, and its flesh is considered superior to either. It feeds on small fish and crustacea; and is in highest perfection for the table in February, March, and April. It is caught on various parts of our coasts, averages about eight or nine inches in length, and is well known in the London markets.

THE LEMON DAB, SMITH DAB, OR SMEAR DAB. (*Pleuronectes levis*), is much larger than the preceding, more rare, and its flesh is equally esteemed. It approaches nearer to a rhomboid in form than any of the genus; and is a handsomer fish than the common Dab, on account of the various shades of reddish brown and yellow which are seen on its upper side. The body is smooth, and covered with a mucous secretion: the head is very small; the eyes are placed very near

each other; and the mouth is full of small teeth.

THE LONG DAB (*Pleuronectes limandoideus*), as its name imports, greatly exceeds the other species in length, approaching, in fact, much nearer to that of the sole; the form of the body being an elongated oval, almost equally pointed at both ends. It is covered with harsh scales; is an inhabitant of the northern seas; and preys on small crabs and other crustaceous and molluscous animals.

DACE. (*Cyprinus leuciscus*.) The Dace, or, as it is sometimes called, the Dare, or Därt, is a fish of the *Cyprinidae* family, and is rather like the Roach, both in habits and appearance, but the former is more local and less plentiful than the latter. It is found in clear and quiet streams, and feeds upon worms and other soft substances: it is

DACE.—(CYPRINUS LEUCISUS.)

gregarious, extremely vivacious, and, like the Trout, it will occasionally rise either at the day-fly, or at an artificial fly. The head of the Dace is small, and the muzzle pointed; the back is slightly elevated, and the tail much forked; the scales are rather small, the sides and belly silvery, and the general form of the body elegantly shaped. During the months of April and May the Dace is in the highest season. "The Dace," says Mr. Yarrell, "is frequently used as bait for Pike in trolling, on account of its silvery brightness; but where live bait are required, as for night hooks, Roach are preferable, on account of their being more tenacious of life." Although this fish, in warm weather, seldom refuses a fly at the surface of the stream, and thereby affords an expert angler much diversion; during the cold months the bait must be sunk within three inches of the bottom.

DACELO. A genus of Kingfishers, from New Holland. For an account of them we are indebted to Mr. Gould. [See KINGFISHER.]

DACNIS. A genus of small and elegant Passerine birds inhabiting Mexico. The colour of the body is cerulean blue; the forehead, shoulders, wings, and tail are black; and it has a sharp, conical bill.

DACOLYTHUS. An appellation given to a small fish, a species of the Loach, from two to three inches long. The head is broader and flatter than the rest of its body, which is brown with black spots: there are two beards on each side of the upper jaw, and on the gill-covers are two sharp prickles. It is partial to shallow brooks with stony bottoms.

DACTYLOPTERUS. A genus of Acanthopterygious fishes, the generic characters

of which are, a large and long flat head, rising suddenly from the muzzle; the preoperculum furnished with an elongated strong spine; the jaws armed with masses of minute conical teeth; six branchiostegous rays; the sub-pectoral rays numerous, very long, and connected by a membrane; body covered with hard carinated scales. By means of their large fins, these fishes dart out of the water when pursued, and are able to sustain themselves in the air for several seconds. There are only two species; one, the Flying Gurnard (*Trigla volitans* of Linnaeus), which inhabits the Mediterranean; the other, the *Dactylopterus orientalis* of Cuvier, inhabits the Indian seas. Neither of these, however, must be confounded with the common Flying-fish, which belongs to the genus *Eurostus*.

DAGGER [MOTHS]. A name given by collectors to Moths of the genera *Acronycta* and *Diurna*.

DALMATIAN, DANISH, SPOTTED, or COACH-DOG. This variety of the canine race, known by each of the foregoing names, is easily distinguished from all other species by its numerous small black spots. Its form is rather elegant, partaking both of the hound

DALMATIAN DOG

and pointer; its limbs are tolerably stout, and its general appearance is showy. The animal has, however, few claims on us for its services; neither its scent nor its sagacity being such as to render it the useful companion of man. It is kept chiefly as an appendage to the carriage, and shows an instinctive fondness for the stable.

DAPHNIA. A genus of minute Crustaceans, belonging to the order Branchiopoda; the best known and most interesting of which is the *Daphnia pulex* (sometimes termed *Monoculus*, from having but one eye). This animalcule, which is popularly called the Arborescent Water-flea, is a favourite microscopic object. The head is prolonged into a snout, and provided with a single central compound eye: it is also furnished with antennae, which serve as oars, to propel it through the water by a series of short springs or jerks. The *Daphnia pulex* is very abundant in many ponds and ditches, being seen on the surface in the mornings and evenings, as well as in cloudy weather; but seeking the depths of the water during the heat of the day. They are extremely prolific; and when, in the summer time,

they assume a red colour, the swarms which abound in stagnant water give it the appearance of its being occasioned by blood. In this country, Dr. Baird, F.L.S., and Mr. John Lubbock, F.R.S., have thrown great light upon their structure, habits, and development.

DART [MOTHS]. A name given by collectors to Moths of the genus *Agrotis*.

DART-SNAKE. [See ACONTIAS.]

DARTER. (*Plotus*.) The Darters are a genus of web-footed birds, of the Pelican tribe, found near the eastern coasts of the tropical parts of America, and on the western coast of tropical Africa. The general form of their bodies is like that of the gulls: they have a long slender bill, broad at the base, but compressed and pointed at the tip: they perch on trees by the sides of lakes, lagoons, and rivers; and, after hovering over the water, they suddenly dart at their snny prey with unerring aim. Their movements are alike rapid and graceful.

"The DARTER or SNAKE BIRD, (*Plotus melanogaster*)," says Wilson, "seems to have derived its name from the singular form of its head and neck, which at a distance might be mistaken for a serpent. In those countries where noxious animals abound, we may readily conceive that the appearance of this bird, extending its slender neck through the foliage of a tree, would tend to startle the wary traveller, whose imagination had portrayed objects of danger lurking in every thicket. Its habits, too, while in the water, have not a little contributed to its name

DARTER, OR SNAKE-BIRD.
(*PLOTUS MELANOGASTER*)

It generally swims with its body immersed, especially when apprehensive of danger, its long neck extended above the surface, and vibrating in a peculiar manner. The first individual that I saw in Florida was sneaking away, to avoid me, along the shore of a reedy marsh, which was lined with alligators, and the first impression on my mind was, that I beheld a snake, but the recollection of the habits of the bird soon undeceived me. On approaching it, it gradually sank, and my next view of it was at many fathoms distance, its head merely out of the water. To pursue these birds at such times is useless.

as they cannot be induced to rise, or even expose their bodies. Wherever the limbs of a tree project over, and dip into the water, there the Darters are sure to be found, these situations being convenient resting-places for the purpose of sunning and preening themselves, and, probably, giving them a better opportunity than when swimming, of observing their finny prey. They crawl from the water upon the limbs, and fix themselves in an upright position, which they maintain in the utmost silence. If there be foliage, or the long moss, they secrete themselves in it in such a manner that they cannot be perceived unless one be close to them. When approached, they drop into the water with such surprising skill, that one is astonished how so large a body can plunge with so little noise, the agitation of the water being apparently not greater than the gliding of an eel.—Formerly the Darter was considered by voyagers as an anomalous production, a monster partaking of the nature of the snake and the duck; and in some ancient charts which I have seen, it is delineated in all the extravagance of fiction."

DARTER-FISH. [See TOXOTUS.]

DASYORNIS. A genus of insectivorous birds, belonging to the great family of Thrushes, and found throughout the greater part of Southern Australia. The **BUSTLEBIRD** (*Dasyornis Australis*) inhabits reed-beds and thickets, but owing to its reclusive habits is a species familiar to few persons. It carries the tail erect, and threads its way through the thickets with great dexterity; but its powers of flight appear to be very limited. The wings, tail-coverts, and tail, are rufous brown, the latter indistinctly barred with a darker tint; under parts brownish grey; bill brown; legs grayish brown. Another species, of a smaller size, called the **LONG-BILLED BUSTLEBIRD** (*Dasyornis longirostris*), is a native of Western Australia, and bears a very close resemblance both in the character and colouring of its plumage to the one above described.

DASYPROCTA. A genus of Rodent Mammalia. In disposition and the nature of their flesh they resemble Hares and Rabbits, which they in some degree represent in the Antilles and hot parts of America. They employ their fore feet to hold up food to their mouth. [See AOUTRI.]

DASYPUS. A genus of Rodent animals, very remarkable among the Mammalia for the scaly and hard shell-like armour which, divided into regular compartments, covers their head and body, and often the tail. [See ARMADILLO.]

DAY-FLY, [See EPHEMERA.]

DECAPODA. An order of Crustacea, containing those in which we find the highest general organization, the most varied habits, and such as are the most useful to man as food. Their growth is slow, and their habits are mostly aquatic: they are naturally voracious; and they are armed with a pair of powerful claws, by which they

seize their food, and convey it to the mouth. In this order are included Crabs, Lobsters, Prawns, Shrimps, &c. [which see]. For the history of the British species, see Dr. Leach's "Malacostraca," or, as more easily accessible, the elegant work on British Crustacea, by Professor Bell, in which are figures and descriptions of all the British species.

DEATH'S-HEAD HAWK-MOTH. A remarkable Lepidopterous insect, belonging to the family *Sphingidæ*. [See *ACHERONTIA ATROPOS*.]

DEATH-WATCH. (*Anobium tessellatum*.) Among the popular superstitions which the almost general illumination of modern times has not been able to obliterate, as Dr. Shaw very truly observes, the dread of the Death-watch may well be considered as one of the most predominant; yet it must be allowed to be a very singular circumstance that an animal so common should not be more universally known, and the peculiar noise which it occasionally makes be more universally understood. The insect in question is a small beetle belonging to the timber-boring genus *Anobium*; and the popular superstition alluded to is, that when its beating is heard, it is a sign that some one in the house will die before the end of the year. It is chiefly in the advanced state of spring that this little creature commences its sound, which is no other than the call or signal by which the male and female are led to each other, and which may be considered as analogous to the call of birds; though not owing to the voice of the insect, but to its beating on, or striking, any hard substance with the shield or fore-part of its head. The prevailing number of distinct strokes which it beats is from seven to nine or eleven; and this very circumstance may perhaps still add to the ominous character which it bears among the vulgar. These sounds or beats are given in pretty quick succession, and are repeated at uncertain intervals; and in old houses where the insects are numerous, may be heard at almost any hour of the day; especially if the weather be warm. The sound exactly resembles that which may be made by tapping moderately hard with the finger-nail on a table. The insect is of a colour so nearly resembling that of decayed wood, viz. an obscure greyish brown, that it may for a considerable time elude the search of the inquirer. It is about a quarter of an inch in length, and is moderately thick in proportion, and the wing-shells are marked with numerous irregular variegations of a lighter cast than the ground-colour. It is singular that this insect may so far be familiarized as to be made to beat occasionally, by taking it out of its confinement, and bending on a table or board, when it will readily answer the noise, and will continue to beat as often as required. I cannot conclude this slight account of the Death-watch, says our author, without quoting a sentence from that celebrated work the *Pseudodoxia Epidemica* of the learned Sir Thomas Brown, who on this subject thus expresses himself: "He that could eradicate this error from

the minds of the people would save from many a cold sweat the meticulous heads of nurses and grandmothers." In their larva state these insects greatly injure old furniture, by perforating numerous small round holes in it.

DEER. (*Cervus*.) Among the various animals which embellish the forests and animate the solitudes of nature, none are superior to the cervine race. These well-known ruminants are distinguished from the antelopes by their horns, which are composed of a bony substance, caducous, or falling off annually, and again renewed of a larger size than in the preceding year. The form of these is various. Sometimes they

SKULL OF STAG.

spread into broad palms, which send out sharp snags around their outer edges; sometimes they divide fantastically into branches, some of which project over the forehead, whilst others are reared upward in the air, or they may be so reclined backwards, that the animal seems almost forced to carry its head in a stiff, erect posture: yet, in whatever way they grow, they appear to give an air of grandeur to the animal. It may, then, speaking in general terms, be said, that the easy elegance of their form, the lightness of their motions, their size, their strength, their fleetness, and the extraordinary development of those branching horns, which seem fully as much intended for ornament as defence, all contribute towards placing them in the foremost rank of quadrupeds.

RED DEER, or STAG. (*Cervus elaphus*.) Before we speak of the habits &c. of this noble animal, it will be well to enter into a few particulars relative to its distinguishing characteristic, the horns. The first year the stag has properly no horns, but only a kind of corneous excrescence, short, rough, and covered with a thin hairy skin; the second year the horns are single and straight; the third year they have two antlers; the fourth, three; the fifth, four; and the sixth, five. When arrived at the sixth year, the antlers do not always increase; and though the number may amount to six or seven on each side, the Stag's age is then estimated rather from the size and the thickness of the branch that sustains them, than from their number.

The proportional length, direction, and curvature of the antlers vary; and it often happens that there is one more or less on the

RED DEER—MALE.—(*CERVUS ELAPHUS*)

one side than on the other: the horns also become larger, the superficial furrows more marked, and the burr is more projecting. Notwithstanding their magnitude, these horns are annually shed in the spring of the year, and succeeded by new ones. Of the old horns, which are of a solid, firm texture, a variety of domestic articles are made; but while young they are remarkably soft and

RED DEER.—FEMALE AND YOUNG
(*CERVUS ELAPHUS*.)

tender; and the animal, as if conscious of its want of power, instantly retires from the rest of the herd, and, hiding itself in thickets and unfrequented places, ventures abroad for the sake of pasture only at night. It is nearly three months before the new horns attain their full growth and solidity; and then, by rubbing them against the boughs of trees, they at length clear them of that covering of skin, which had before contributed to their growth and nourishment. "The growth of the horns," says Mr. Bell, "is an astonishing instance of the rapidity of the production of bone under particular circumstances, and is certainly unparalleled in its extent in so short a period of time. A full grown Stag's horn probably weighs

twenty-four pounds; and the whole of this immense mass of true bone is produced in about ten weeks. During its growth the branches of the external carotid arteries, which perform the office of secreting this new bone, are considerably enlarged, for the purpose of conveying so large a supply of blood as is necessary for this rapid formation. These vessels extend over the whole surface of the horn as it grows, and the horn itself; at first soft and extremely vascular, so that a slight injury, and even merely pricking it, produces a flow of blood from the wound. It is also protected at this time with a soft, short, hairy or downy coat, which is termed the velvet; and hence the horns are said to be in 'the velvet' during their growth."

The Stag is supposed to have been originally introduced into our own island from France, where it is very common: but it has been in a great degree expelled from most parts of this kingdom to make way for the common, or Fallow Deer, the venison of which is far superior to that of the Red Deer, and the animal itself of a more manageable and placid disposition. The Stag has a fine eye, an acute smell, and a good ear. When listening, he raises his head and erects his ears. When going into a coppice or other half-covered place, he stops to look round him on all sides, and scents the wind, to discover if any object be near that might disturb him. Though a simple, he is a curious and crafty animal. When hissed or called to from a distance, he stops short, and looks steadfastly, and, with a kind of admiration, at horses or men; and if the latter have neither arms nor dogs, he moves on without betraying any symptoms of alarm. He eats slowly; and after his stomach is full, he lies down and ruminates at leisure.

In Dr. A. T. Thomson's notes to an edition of "THE SEASONS," by his celebrated namesake, we find appended to line 454, (*Autumn*),—

"The big round tears run down his dappled face;"

the following very apposite remarks:—"This supposed peculiarity of the Stag to shed tears is noticed by several poets, but by none so strikingly as by Shakspeare* and our author: but, indeed, it is not wonderful that it was the popular belief before it was noticed by poets, for the eyes of the Stag, and nearly all the deer tribe, display a peculiarly weeping aspect. This is more obviously displayed in the male than in the female. It depends on a remarkable glandular sinus, *crumen*, or *tear-pit*, placed at the inner angle of each eye, close to the nose without having any communication with it, or with what are termed the lachrymal

passages. It is composed of a fold of the skin, and is capable of being opened and shut at the pleasure of the animal. It is furnished at the bottom with a gland, which secretes an oily, viscous substance, of the colour and consistence of the wax of the ears, and which hardens and becomes black when exposed to the air. The precise function of this organ is unknown, although many conjectures have been offered in explanation of it: and there can be no doubt that it serves some important purpose in the economy of the animal. The moistened moving edges of the sinus have been mistaken by general observers and the poets, for precious tears let fall over that part of the eyelids; and, in our love for the romantic, we almost regret to be undeceived."

In winter and spring this animal rarely ever drinks, the dews and tender herbage being sufficient to satisfy his thirst; but during the parching heats of summer, he not only frequents the brooks and springs, but searches for deep water wherein to bathe and refresh himself. He swims with great ease and strength, particularly when he is in good condition, his fat contributing to his buoyancy. His voice is stronger, louder, and more tremulous, in proportion as he advances in age; and during the rutting season it is really fearful. The cry of the *hind*, or female, is not so loud as that of the male, and she is never excited but through apprehensions for the safety either of herself or her young. Like all the rest of the Deer tribe, except the Elk, the female is destitute of horns; she is also more feeble and unfit for hunting than the male. The pairing season is in August; the time of gestation is between eight and nine months; and she seldom produces more than one at a time. The usual season of parturition is about May, during which these animals are very assiduous in concealing and tending their young; nor is this a needless precaution, since almost every animal of the canine or feline kind is then an active enemy; nay, unnatural as it may seem, the Stag himself is also one of their most dangerous assailants. At this season, therefore, the courage of the male seems to be transferred to the female; for she resolutely defends her offspring; and if pursued by the hunter, exposes herself to great apparent danger, for the purpose of diverting his attention from the object of her parental regard. The *Calf* (the name by which the young of this animal is called) never quits the dam during the whole summer; and in winter, the hind, together with all the males under a year old, assemble in herds, which are more or less numerous in proportion to the mildness or severity of the season. At the approach of spring they separate, none but those of the age of one year remaining associated. They are, however, generally gregarious, and only danger or necessity can possibly divide them.

"When a Stag stands at bay," says the accomplished Editor of Thomson's *Seasons*, before quoted, "his instinct leads him to do so in a river or a lake, if either be near; in which case he has a great advantage over the dogs, for he firmly stands and holds his

*—"the big round tears
Coursed one another down his innocent nose
In piteous chase; and thus the hairy fool,
Much marked of the melancholy Jaques,
Stood on the extremest verge of the swift brook
Augmenting it with tears."

As You Like It, act ii. sc. 1.

position, whilst they swim powerless around him. On land, even, a Stag at bay has great advantage over the hounds, who exhaust themselves with their clamour, whilst he is in a comparative state of rest, and recovers his wind." Powerful as the Stag is, he has never been known to attack a man, unless he has been driven into a corner, and hard pressed, without the means of escape. With regard to hunting the Stag, the pursuit, as carried on in the Highlands, is one capable of rousing all the manly ardour and energy of youth and manhood, whilst all the powers of both body and mind are called into action. The beauty, graceful, and magnificent bearing of the animal, his sagacity in evading the stratagems of the hunter, or deer stalker, and his courage when at bay, add greatly to the pleasure of the chase. In stalking deer, the animal is generally shot; but if he is only wounded, and has power to fly, then the dogs are slipped to the pursuit. But, in olden times, the chief reliance for pulling and killing the deer, was in the dogs; and the fleetness and courage of their hounds were the pride of nobles and kings."

The food of Stags varies according to the season. In autumn they search for the buds of green shrubs, the flowers of broom or heath, the leaves of hrambles, &c. During the snows of winter they feed on the bark and moss of trees; and in mild weather they browse in the fields. In the present cultivated state of this country, Stags are almost unknown in their wild, natural condition; and such as remain amongst us are kept under the name of Red Deer, together with the Fallow Deer; but their excessive ferocity during the rutting season, and the coarseness of their flesh, have contributed in a great measure to effect their almost total extermination. In Scotland, however, they still exist in considerable numbers; and though it was deemed necessary to abolish Stag-hunting by act of parliament, in consequence of the multitudinous gatherings of the clans, upon this pretext, being often made subservient to political purposes, "a Stag-hunt is even in the present day the scene of much of the excitement and profuse hospitality by which this noble sport was characterized in days of yore."

"The Stag is an ancient denizen of the forests of this country. From the most remote periods, it has been the favourite object of the chase; and the severe forest-laws of our earlier Norman monarchs sufficiently attest the importance which they attached to the sport. The afforesting of vast tracts of country, by which not only single cottages were destroyed, but whole villages swept away, and churches desecrated and demolished, was the fertile source of misery to the poorer inhabitants, and of injustice to the ancient proprietors of the soil; and the cruel inflictions of the oppressive laws which were enacted to preserve the Deer, increased tenfold the curse arising from this tyrannical passion for the chase,—for it was a crime less severely penal to kill a man than to destroy or take a Deer."

"The ancient customs and laws of 'Venerie,' that noble science which our simple

ancestors looked upon as one of the first accomplishments of the high-bred noble, and a knowledge of which was essential to his education, were formal and technical to a most absurd and ludicrous degree. A few of the terms, betokening the different ages of the Stag and Hind, are still retained, though somewhat altered. The young of either sex is called a CALF; after a few months the male becomes distinguished by the growth of the bossets, or frontal protuberances, on which the horns are afterwards developed, which during the first year are merely rounded knobs, from whence he takes the name of KNOBBIE. In the second year they are longer and pointed, and are called dags, and the animal has now the name of BROCKET. In the third year, the first, or brow antler, has made its appearance, and the Deer becomes a SPAYAD. In the fourth, the bez-antler is added, and he is then termed a STAOGARD. He is a STAG in the fifth year, when the third antler, or royal, appears; and in the sixth, the commencement of the sur-royal, or crown, is formed; when he takes the name of HART, which name he retains through life. At this time he is called a Hart or Stag of ten, probably because the branches, including the sur-royal, frequently amount to that number. After the seventh year he is said to be crooked, or palmied, or crowned, according to the number of branches composing the sur-royal. The female is a Calf in the first year, a Brocket's sister in the second, and in the third, and ever afterwards, a Hind."—*Bell's British Quadrupeds.*

VIRGINIAN DEER. (*Cervus Virginianus*.) This species is found in vast herds in the northern parts of America, and is an animal of great importance to the Indian natives. They are of a light brown colour, and about the size of the Fallow Deer, but their ails are longer. Their horns are slender, bend greatly forwards, and have numerous branches on the interior sides, but no brow antlers. They are of a restless and wandering disposition, and in hard winters are observed to feed much on the different species of *usnea* or string moss, which hangs from the trees: they are also fond of resorting to places impregnated with salt, and vulgarly called salt-licks; and it is at these favourite haunts that the hunters generally succeed in killing them. Their flesh, though dry, is very valuable to the Indians, who cure it for their winter provision.

PORCINE DEER. (*Cervus porcinus*.) An Indian species of the cervine genus; about two feet three inches in height; the body clumsy; the legs fine and slender; and the tail about eight inches long. It has slender trifurcated horns, about a foot in length: the colour, on the upper part of the neck, body, and sides is brown; the belly and rump lighter.

[For other species of the genus *Cervus*, or Deer tribe, see *AXIS*—*ELK*—*FALLOW-DEER*—*MUNJAC*—*REINDEER*—*ROEBUCK*—*WAPITI*.] We may mention that there are many species of Deer, chiefly found in South America and in Asia; specimens of most of

the species being in the collection of the British Museum, and many of them are to be seen alive in the Gardens of the Zoological Society, and used to adorn the noble menagerie of the Earl of Derby (President of that Society), at Knowsley, Lancashire.

DEINACRIDA. A genus of Orthoptera belonging to the *Gryllida* or Cricket tribe. Our figure is copied from the one that accompanies Mr. White's description in the *Zoology of the Voyage of H. M. S. Erebus and Terror*. Mr. W. Stephenson, speaking of it in his remarks on the entomology of New Zealand, says, "It is a peculiarly formidable insect, found in old trees, secreting

NEW ZEALAND GRAND CRICKET.
(*DEINACRIDA HETERACANTHA*.)

itself in rents and crevices. It is an abundant species in New Zealand, and is carnivorous. It is called by the Maories *Weta*." The male is distinguished from the other sex (here figured) by its enormous head, the bite of which is very severe. Both sexes are apterous, the female being very prolific in ova. Mr. Stephenson believes there are more than one species of this genus. It is allied to the genus *Anastotomus* of Mr. G. R. Gray.

DELPHINIDÆ. The Dolphin tribe, a family of cetaceous animals, characterized by the moderate size of the head, and usually by the presence of teeth in both jaws. It includes, with the Dolphin and Porpoise, many animals which are ordinarily called Whales; a considerable number of which occasionally visit the northern coasts of Britain. They are in general voracious feeders; and their flesh is for the most part rank, oily, and unwholesome. [See WHALE.]

DEMOISELLE. (*Anthropoides Virgo*.) The Demoiselle, or Numidian Crane, is remarkable for the grace and symmetry of its form, and the elegance of its deportment. It measures three feet three inches in length; and has a beak two inches and a half long, the base of which is greenish and the tip red: the irides are crimson: the crown of the head is cinereous; the rest of the head, and neck, black: the feathers of the breast are long and drooping: the under parts of the body, from the breast, the back, and the tail,

are bluish ash; the latter and the quills are tipped with black; and the legs are black. This gallinatorial bird is a native of many parts of Asia and Africa; and is to be met with along the whole of the southern and eastern shores of the Mediterranean. It delights in damp and marshy places, frequenting those parts in search of small fishes, frogs, &c., which are its favourite food. It is easily domesticated.

There is another species, called the **CROWNED DEMOISELLE** (*Anthropoides Paronia*), which is less than the one above described, and about the size of the common heron. The crown of the head is covered with soft black feathers, like velvet; on the hind part

(CROWNED DEMOISELLE
(*ANTHROPOIDES PARONIA*.)

is a tuft of stiff hair, which spreads out on all sides in a globular form; this is four inches in length, and of a reddish brown colour: the sides of the head are bare of feathers; and on each side of the throat hangs a kind of wattle. The general colour of the bird is a bluish ash: the feathers on the fore part of the neck are very long, and hang over the breast; wing-coverts white; the greater ones incline to rufous, and those farthest from the body to black: the greater quills and tail are black, and the secondaries chestnut. The female is black where the male is blue-ash, and the wattles on the throat are wanting. This bird is a tame species, and, like the preceding, is often kept in aviaries: it runs very fast; flies strong, and is able to keep on the wing for a long time together. Another species, the **STANLEY DEMOISELLE** (*Anthropoides paradi-sa*), is even more elegant than either of the preceding; it is of a light ashy blue colour.

DENDRERPETON. [See SUPPLEMENT.]

DRENDROCOLAPTES, or **HOOKEBILLED CREEPERS.** A genus of Tenuirostral Birds, with the bill generally long and curved, the tail feathers stiff and pointed to assist the birds in climbing; the claws are long and curved. There are several species, natives of South America; their general colour is brown, with grey mixtures, and in most of the species there are whitish lines or spots about the head and neck: these birds are marked features in the Fauna of South America. [See FURNARIUS.]

DENDRODUS. [See SUPPLEMENT.]

DENDROLAGUS, or **Tree Kangaroo.** A

genus of Marsupials. Two species, *D. ursinus* and *D. inustus*, were discovered by M. S. Muller in New Guinea. These were found at Triton Bay, and they also inhabit the interior of the country. They are arboreal in their habits, climbing trees with the utmost facility. The tail is considerably elongated, and in one species (the *D.*

TREE-KANGAROO. — (DENDROLAGUS.)

inustus) of nearly equal thickness throughout. The *D. ursinus* is of a deep blackish brown; the *D. inustus* paler. Now that New Guinea is taken into the possession of the British, specimens and full particulars of this interesting genus may soon be looked for.

DENDROPHYLLIA. The name given to a genus of Polypt, or Madreporcs, of coral-like structure. They are of arborescent forms, the stem sending out branches, instead of remaining simply columnar; and these branches again subdividing. The whole structure is covered with a gelatinous or fleshy substance, which, although it has no direct communication with the stomach, seems to constitute the animal, of which the Polypes are only subordinate parts.

DENDROSAURA, or TREE LIZARDS. The name of a tribe of Reptiles, containing the Chamæleons, and used by Mr. Gray in his excellent Descriptive Catalogue of the Lizards in the British Museum. The scales of the belly, of the side, and of the back, are granular, and in circular bands; the tongue is worm-like and elongate, and very extensible. The eyes are globular, very mobile, covered with a circular lid pierced with a small central hole. The toes are formed into two grasping opposable groups, which fit them admirably for living on trees. [See CHAMÆLEON.]

DENTIROSTRES. The name of a tribe of birds, characterized by having a notch and tooth-like process on each side of the margin of the upper mandible. They manifest rapacious habits, and prey on smaller and weaker birds. The *Butcher-bird* will serve as an example of this tribe.

DERMESTES : DERMESTIDÆ. A genus and family of Coleopterous insects, the antennæ of which are elevated and perforated transversely. The larvæ or grubs of this tribe devour dead bodies, skins, leather, and

almost any animal substance, and are exceedingly destructive to books and furniture. "Although obnoxious in these respects, the insects of this family are of infinite service in the economy of nature, by causing the rapid decomposition of animal matter into a substance fitted for the improvement of the soil, and by their labours, united with those of the Silphæ, Necrophori, &c., destroying such portions of these remains as are left untouched by the Flesh-flies, which only consume the soft portions of the carcasses. Like the perfect insects, their larvæ are seldom observed upon the surface of the matters which they attack." — Westwood. This gentleman further observes (in a note), "In some of the Egyptian mummies lately opened, a great number of dead specimens of several species of *Dermestes* have been discovered in the interior of the body, together with a number of their larvæ, also dead: hence, from the circumstance of these larvæ being found dead in a situation which appears at one time to have been congenial to them, I am induced to think that these insects must have found their way into the body previous to the final operation of embalming, whereby they were destroyed."

The complete insects are mostly of a lengthened oval shape, and have a habit of withdrawing the head beneath the thorax when handled. — One of the most familiar species

BACON BEETLE.
(DERMESTES
LARDARIUS.)

is the *Dermestes lardarius*, or Bacon-beetle, which is about a third of an inch in length, and of a dusky brown colour, with the upper half of the wing shells whitish or ash-coloured, and marked with black spots. — Another species, seen in almost every house during the spring and early part of the summer, is the *Attagenus Feltio*. It measures scarcely a quarter of an inch in length, and is of a very dark brown or blackish colour, with a white speck on the middle of each wing-shell.

DESMAN, or MUSK-RAT. (*Myogale moschata*.) An insectivorous animal, aquatic in all its habits, and nearly equal in size to

DESMAN, AND FOOT. —
(MYOGALE MOSCHATA.)

the Hedgehog. Its muzzle is elongated into a small, very flexible proboscis, which

is constantly in motion. It has a long tail, scaly and flattened at the sides; membranous feet; eyes very small; and no external ears. This animal is very common along the rivers and lakes of Southern Russia, where it feeds on worms, the larvæ of insects, and particularly on leeches, which it easily withdraws from the mud by means of its flexible proboscis. It never comes voluntarily on shore, but is often taken in the nets of the fishermen. Its burrow, excavated in a bank, commences under water, and ascends to above the level of the highest floods. Under the tail of the Desman are two small follicles containing a kind of unctuous substance, of a strong musky odour, from which the name of *Musk-rat* is given to it.

DEW [MOTHS]. A name given by collectors to Moths of the genus *Selina*.

DIADEM SPIDER. (*Epeira diadema*.) This spider, so common in the autumn, belongs to Walckenaer's genus *Epeira*. Its body, when full grown, is nearly as large as a hazel nut, is of a deep chestnut brown colour, and

DIADEM SPIDER.—(*EPEIRA DIADEMA*.)

the abdomen beautifully marked by a longitudinal series of round milk-white spots, crossed by others of a similar appearance, so as to represent in some degree the pattern of a small diadem. It is chiefly seen during the autumnal season in our gardens, where, in some convenient spot or shelter, it forms a large, round, close web of yellow silk, in which it deposits its eggs, guarding this web with a secondary one of a looser texture. The young are hatched in the ensuing May, the parent insects dying towards the close of autumn. At the tip of the abdomen are placed five papillæ or tents, through which the spider draws its thread. The eyes, which are situated on the upper part of the thorax, are eight in number, placed at a small distance from each other. The fangs with which the animal wounds its prey are strong, curved, sharp-pointed, and each furnished on the inside, near the tip, with a small oblong hole or slit, through which is discharged a poisonous fluid into the wound made by the point itself. The feet are of a highly curious structure; the two claws with which each is terminated being furnished on its under side with several parallel processes resembling the teeth of a comb, and enabling the spider to manage with the utmost facility the threads in its web, &c. [See SPIDER.]

DIAMOND BEETLE. (*Entimus*.) This splendid Coleopterous insect belongs to the

family *Curculionidæ*, and contains two or three species. It is very abundant in some parts of South America. It is often, with a magnifying glass of no great power, formed

DIAMOND BEETLE.—(*ENTIMUS NOBILIS*.)

into a very pleasing toy to amuse young people. There are small species of *Curculionidæ* in our own island, however, which are scarcely less brilliant when magnified under a good light, and with sufficient power.

DIAPERIS. [See TAXICORNES.]

DICÆUM. A genus of Tenuirostral Birds, allied to the CREEPERS; they do not use their tails as these birds do; and they are generally brilliant in colour, having more or less of scarlet in their plumage. Species occur in Asia, its islands, and in Australia.

DICHOBUNE. [See SUPPLEMENT.]

DICHODON. [See SUPPLEMENT.]

DICOTYLES. [See PECORÆ.]

DICRONOCEPHALUS. A genus of Coleoptera belonging to the family *Cetoniidæ*, described by Mr. Hope. The male, which is the only sex at present known, is remarkable for the two horns on the head, which are bent up. The only known species, *Dicronocephalus Wallichii*, is a native of

DR. WALLICH'S BEETLE.
(*DICRONOCEPHALUS WALLICHII*.)

Northern China, where it has been lately found by Mr. Robert Fortune, the Botanist. It is of a yellowish gray colour, and it is at present very rare in collections (there is one, however, in the British Museum); but, like its congeners, *Naryctus* and *Cyphonocephalus*, from India, and *Mycteristes* and *Phædimus*, from the Eastern Islands, the

active researches of Indian officers and colonists will make these pretty and singular insects more common.

DICYNODON. [See APPENDIX.]

DIDELPHIDÆ. A family of quadrupeds belonging to the order *Marsupialia*, and consisting of the genus *Didelphis*, or Opossum. They are restricted to America. They are characterized by having ten incisors above and eight below, the canines being one on each side of either jaw, and the molars seven, the four last, or true molars, being crowned with sharp tubercles. The limbs are short; the feet plantigrade; and the toes, which are five on each foot, armed with sharp, strong, curved claws, except the inner toe or thumb on the hinder feet, which is opposable and destitute of a nail. The tail, except at the base, is scaly and naked; and it is usually more or less prehensile. In some species the pouch is entirely wanting, being indicated only by a slight fold of the skin. [See OROSSUM.]

DIDUNCULUS. A genus of birds found in the South Sea Islands. [See GNATHODON.]

DIDUS. [See *Dodo*, p. 183.]

DIMERA. A section of the order *Hemiptera*, comprising much smaller insects than those included in the section *Trimera*, and distinguished from them by having only two joints in the tarsi; with antennæ longer than the head, and composed of from six to ten filiform joints; whilst they differ from the *Monomera* by the winged individuals possessing four wings, the anterior being ordinarily of the same membranous texture as the posterior. The section consists of the families *Psyllidæ*, *Aphidæ*, and *Aleyrodidæ*.

DIMORPHODON. [See SUPPLEMENT.]

DIMYARIA. The name given to the second order of *Conchifera*, or Bivalv. Shells. It contains a great number of families, which may be grouped into four divisions, arising partly from the shape of the foot of its moluscous inhabitant, but chiefly from the more, or less perfect manner in which the valves close upon each other.

DINGO, or AUSTRALIAN DOG. This species of the canine race has a very wolf-like appearance. The ears are short and erect; the tail rather bushy; the hair, which

DINGO.—(*CANIS FAMILIARIS AUSTRALASIE*.) is of a reddish dun colour, is long, thick, and straight. This dog is extremely fierce, and

has the same sort of snarling and howling voice as the larger kind of dogs have in general; though by some it has been erroneously said neither to bark nor growl. There is good reason, however, to believe that the Dingo is the descendant of a race once domesticated, which has returned to its wild state.

DINORNIS. A genus of birds allied to the Ostrich tribe, now only found in a fossil state in New Zealand, whence many bones have been sent to this country. One of the species must have been at least fourteen feet high, and it is believed that some specimens may have been still higher. It is known to the natives by the name of *Moo*. For details of its anatomy, the reader should consult Prof. Owen's elaborate Memoir in the third and fourth volumes of the Zoological Society's Transactions.

DINOSAURIA. [See SUPPLEMENT.]

DINOTHERIUM. A genus of extinct herbivorous quadrupeds, of gigantic dimensions; but as only fragments of this huge creature have yet been found, the size of the entire animal cannot be accurately given.

SKULL OF *DINOTHERIUM GIGANTEUM*.

A skull of one was disinterred at Epplesheim, in Hesse Darmstadt, in 1836, measuring about four feet in length and three in breadth; from which, according to the calculations of Cuvier and Kaup, the *Dinotherium* is supposed to have attained the length of eighteen feet. Dr. Buckland, who paid great attention to the remains of this immense specimen of extinct Mammalia, is decidedly of opinion that it was an aquatic animal. "It is mechanically impossible," he observes, "that a lower jaw, nearly four feet long, loaded with such heavy tusks at its extremity could have been otherwise than cumbrous and inconvenient to the quadruped living on dry land. No such disadvantage would have attended this structure in a large animal destined to live in water; and the aquatic habits of the family of Tapirs, to which the *Dinotherium* was most nearly allied, render it probable that, like them, it was an inhabitant of fresh-water lakes and rivers," &c. The Doctor subsequently

says, "Professor Kaup and Dr. Klipstein have recently published a description and figures of this bead, in which they state that the very remarkable form and dispositions of the hinder part of the skull show it to have been connected with muscles of extraordinary power, to give that kind of movement to the head which would admit of the peculiar action of the tusks in digging into and tearing up the earth. They further observe that my conjectures respecting the aquatic habits of this animal are confirmed by approximations in the form of the occipital bone to the occiput of *Cetacea*; the *Dinotherrium*, in this structure, affording a new and important link between the *Cetacea* and the *Pachydermata*."

DIODON. A remarkable genus of *Plectognathi*, or bony fishes with soldered jaws.

The **DIONON HYSTRIX**, commonly termed the Sea-Porcupine, is of a nearly spherical form, sometimes measuring not less than two feet in length; but it possesses the power of inflating or contracting itself at pleasure by means of an internal skin or membrane situated beneath the exterior or spiny covering. Its colour is a pale grey, the back being of a somewhat deeper cast; and the whole body is marked at the base of each spine by a round black spot; the fins being also spotted. When taken by a line and hook, it inflates its body and elevates its spines to the highest possible degree, as if endeavouring to wound in all directions; nor can it be touched without danger until it is dead. It is a native of the Indian and American seas; and its flesh is coarse and worthless.

The **OBLONG DIONON** (*Diodon atinga*) differs from the former in being of a more lengthened shape, and in having the spines rather round than triangular. Its general colour is grey, deeper on the back, and with a cast of pink on the lower parts like the *Diodon Ilystrix*: It is marked with numerous round black spots; but it is only from twelve to fifteen inches in length. Unless very carefully cleaned it is dangerous to eat it; for if not absolutely poisonous, the flesh is highly unwholesome. It is a native of the Indian and American seas.

Besides the above, there is the **ROUND DIONON** (*Diodon orbicularis*), about nine or ten inches in length; which is considered a poisonous fish: **PLUMER'S DIONON** (*Diodon Plumieri*), a species very nearly allied to the Oblong Diodon; and the **PATCHED DIONON** (*Diodon liturosus*), which inclines to a globular shape, and is marked on each side of the body with an oval patch and two transverse ones; and on the back a round spot encircling the dorsal fin: spines white with brown tips, and all the fin, greenish yellow.

"One day," says Mr. Darwin (while on the coast of Brazil), "I was amused by watching the habits of a Diodon, which was caught swimming near the shore. This fish is well known to possess the singular power of distending itself into a nearly spherical form. After having been taken out of water

for a short time, and then again immersed in it, a considerable quantity both of water and air was absorbed by the mouth, and perhaps likewise by the branchial apertures. The process is effected by two methods; the air is swallowed, and is then forced into the cavity of the body, its return being prevented by a muscular contraction which is externally visible; but the water, I observed, entered in a stream through the mouth, which was wide open and motionless; this latter action must therefore depend on suction. The skin about the abdomen is much looser than that of the back; hence, during the inflation, the lower surface becomes far more distended than the upper; and the fish, in consequence, floats with its back downwards. Cuvier doubts whether the Diodon, in this position, is able to swim; but not only can it thus move forward in a straight line, but likewise it can turn round to either side. This latter movement is effected solely by the aid of the pectoral fins, the tail being collapsed, and not used. From the body being buoyed up with so much air, the branchial openings were out of water; but a stream drawn in by the mouth constantly flowed through them.

"The fish, having remained in this distended state for a short time, generally expelled the air and water with considerable force from the branchial apertures and mouth. It could emit, at will, a portion of the water; and it appears, therefore, probable, that this fluid is taken in partly for the sake of regulating its specific gravity. This Diodon possessed several means of defence. It could give a severe bite, and could eject water from its mouth to some distance, at the same time it made a curious noise by the movement of its jaws. By the inflation of its body, the papillæ, with which the skin is covered, became erect and pointed. But the most curious circumstance was, that it emitted from the skin of its belly, when handled, a most beautiful carmine red and fibrous secretion, which stained ivory and paper in so curious a manner, that the tint is retained to the present day."

DIOMEDEA. [See ALBATROSS.]

DIPHYLLOBOTRIUM. [See SUPPL.]

DIOPSIS, or TELESCOPE FLY. A very singular genus of Dipterous insects, remarkable for the enormously developed pedicels on which the eyes are situated. They

TELESCOPE FLY.
(*DIOPSIS MACROPTERTHALMA*.)

are found in Western Africa, India, and the Indian islands, some of the species being of considerable size. One species, the *Diopsis Sylkesii*, was observed by the distinguished Indian statistician and naturalist after whom it is named by Mr. G. R. Gray, in countless multitudes in one of the Indian vallies. Hence it is not improbable that the habits of the numerous species composing the genus are similar. It is one of those well-marked and remarkable groups of insects, all the species of which have been described and figured by Mr. Westwood. They are, however, rare in collections; the British Museum possessing many curious species.

DIPLOPTERA, or DIPLOPTERYGA.

A group of Hymenopterous insects, forming the third division of the subsection *Prædones*. These wasps obtain their name from the wings being folded throughout their entire length when at rest. The antennæ are generally elbowed, and either filiform or thickened at the tips: the palpi are short and filiform; the maxillæ are long, coriaceous, and compressed; the thorax is oval and entire; and the collar extends laterally to the base of the wings. The body is generally black, more or less spotted with buff, and either quite naked, or very slightly clothed with hairs: the legs are of moderate length, not furnished with organs fitted for the collection of pollen; and the abdomen is ovate. The sting of the females and neuter is very powerful, and has occasionally caused the death of those persons who have been attacked by these insects. This division forms two families, *Eumenidæ* and *Vespidæ*. [See WASP.]

DIPROTODON. [See SUPPLEMENT.]

DIPSAS. A genus of Snakes [which see].

DIPTERA. An order of two-winged insects; of which the common house-fly and blue-bottle fly afford familiar examples. There are, however, some dipterous insects which are destitute of wings; hence it is necessary to notice other peculiarities belonging to this order. Some possess a proboscis and sucker: others have a proboscis and nosucker. They have six legs, furnished with five-jointed tarsi, two palpi, two antennæ, and three ocelli. The mouth in the insects of this order is formed for suction; but there are considerable varieties in the mode in which this is accomplished. Behind the wings are placed a pair of movable slender bodies, termed *halteres*, or balancers, which are kept in continual motion, and are usually present even when the true wings are not developed. The wings are generally horizontal in their position, and transparent; the eyes are generally large, often occupying nearly the whole head. The Diptera all undergo a complete metamorphosis, as far as respects the comparative structure of the larva and the perfect insect; the former being generally cylindrical footless grubs.

The two-winged insects, though mostly of moderate or small size, are not only very numerous in kinds or species, but also extremely abundant in individuals of the same kind, often appearing in swarms of countless

multitudes. Flies are destined to live wholly on liquid food, and are therefore provided with a proboscis, enclosing hard and sharp-pointed darts, instead of jaws, and fitted for piercing and sucking; or ending with soft and fleshy lips, for lapping. In our own persons we suffer much from the sharp suckers and bloodthirsty propensities of gnats and mosquitos (*Culicidæ*), and also from those of certain midges (*Ceratopogon* and *Simulium*), including the tormenting black flies (*Simulium molestum*) of America. The larvæ of these insects live in stagnant water, and subsist on minute aquatic animals. Horse-flies and the golden-eyed forest flies (*Tabanidæ*), whose larvæ live in the ground, and the stinging stable-flies (*Stomoxys*), which closely resemble common house-flies, and in the larva state live in dung, attack both man and animals, goading the latter sometimes almost to madness by their severe and incessant punctures. The winged horse-ticks (*Hippoboscæ*), the bird-flies (*Ornithomyiæ*), the wingless sheep-ticks (*Melophagi*), and the spider-flies (*Nycteribiæ*), and bee-lice (*Brulæ*), which are also destitute of wings, are truly parasitical in their habits, and pass their whole lives upon the skin of animals. Bot-flies or gad-flies (*Cestridæ*), as they are sometimes called, appear to take no food while in the winged state, and are destitute of a proboscis; the nourishment obtained by their larvæ, which, as is well known, live in the bodies of horses, cattle, sheep, and other animals, being sufficient to last these insects during the rest of their lives. Some flies, though apparently harmless in the winged state, deposit their eggs on plants, in the juices of which their young subsist, and are oftentimes productive of immense injury to vegetation; among these the most notorious for their depredations are the gall-gnats (*Cecidomyiæ*), including the wheat-fly and Hessian-fly, the root-eating maggots of some of the long-legged gnats (*Tipulæ*), those of the flower-flies (*Anthomyiæ*), and the two-winged gall-flies and fruit flies (*Ortoides*). To this list of noxious flies, are to be added the common house-flies (*Muscæ*), which pass through the maggot state in dung and other filth, the blue-bottle or blow-flies, and meat-flies (*Lucilæ* and *Calliphoræ*), together with the maggot-producing or viviparous flesh-flies (*Sarcophagæ* and *Cynomyiæ*), whose maggots live in flesh, the cheese-fly (*Piophilæ*), the parent of the well-known skippers, and a few others that in the larva state attack our household stores. Some are entirely harmless in all their states and many are eminently useful in various ways. Even the common house-flies, and flesh-flies, together with others for which no names exist in our language, render important services by feeding, while larvæ, upon dung, carrion, and all kinds of filth; by which means, and by similar services, rendered by various tribes of scavenger-beetles, these offensive matters speedily disappear, instead of remaining to decay slowly, thereby tainting the air and rendering it unwholesome. Those whose larvæ live in stagnant water, such as gnats (*Culicidæ*), the soldier-flies (*Stratiomyidæ*),

&c., tend to prevent the water from becoming putrid, by devouring the decayed animal and vegetable matter it contains. The maggots of some flies live in toadstools and similar excrescences growing on trees; those of others in rotten wood and bark. And, finally, many lay their eggs on caterpillars, and on various other larvæ, within the bodies of which the maggots hatched from these eggs live till they destroy their victims. Besides performing their various appointed tasks in the economy of nature—flies, and other insects, subserve another highly important purpose, for which an allwise Providence has designed them, namely, that of furnishing food to numerous other animals. Not to mention the various kinds of insectivorous quadrupeds, many birds live partly or entirely on insects. The finest song-birds, nightingales and thrushes, feast with the highest relish on maggots of all kinds, as well as on flies and other insects, while warblers, swallows, &c. &c., devour these two-winged insects in great numbers. — The works of Meigen, Wiedemann, Macquart, and Robineau Desvoidy, are the great authorities on this very numerous and every where distributed order of insects.

DIPUS. [See JERBOA.]

DIRT-DAUBER. The name given in the United States to a species of Hymenopterous insect. [See PELOPEUS.]

DISTOMA. [See FLUKE, p. 223.]

DIVERS. (*Colymbidae*.) A genus of aquatic birds, thus described by Bewick:—"The bill is strong, straight, and pointed; the upper mandible longest; the edges of each bending inwards: nostrils linear, the upper part divided by a small cutaneous appendage: tongue long, pointed, and serrated on each side near the base: thighs placed far backward: legs thin and flat, and extended horizontally: toes four in number; the exterior the longest; the back one small, and joined to the interior by a thin membrane: tail short, consisting of twenty feathers. These birds are broad, flat, and long-bodied, and swim in a squat position on the water."

The GREAT NORTHERN DIVER. (*Colymbus glacialis*.) measures upwards of three feet in length, and four feet six inches in breadth. The bill is black and strong, and to the corners of the mouth is four inches long; the head and neck are of a deep black, glossed with green and purple: the hind part of the latter being streaked with a large white band shaped like a crescent; exactly under the throat is another band; and both are marked with black oblong strokes pointing downwards. The lower part of the neck is a deep black, tinged with a rich purple gloss; the breast and under side of the body is wholly white; the sides of the breast are marked with black lines; and the back, the coverts of the wings, and the scapulars, are black, thickly marked with white spots. The tail is very short, and almost hid by the scapulars; the legs and feet are black. The female is less than the male, and her whole upper plumage

inclines more to brown. This bird inhabits the north of Europe and the Arctic coasts, and is sometimes, though rarely, seen in England. It seldom quits the sea, or retires

GREAT NORTHERN DIVER.
(*COLYMBUS GLACIALIS*.)

inland, except during the period of incubation, when it repairs to the borders of freshwater lakes; and the female deposits two large eggs of a pale clear yellowish colour, marked with very large and small spots of ashy-purple. Fish is the principal food of this species, and the herring in particular, the fry of fish, crustaceans, and marine vegetables.

The RED-THROATED DIVER. (*Colymbus septentrionalis*.) This species is about two feet in length, and three feet four inches in breadth. The sides of the head, neck, and throat are mouse colour; the top of the head is spotted with black; the hinder and lower part of the neck are longitudinally rayed with black and white; the upper fore part of the neck, to the throat, is of a deep chestnut-red; the breast and under parts of the plumage are pure white: the sides, the back, and the rest of the upper parts are blackish brown in the very old birds, but in those of the age of three or four years they are slightly sprinkled with small white spots. The male and female are nearly alike in their plumage. This species inhabits the same cold countries as the other Divers, and its manners and habits do not differ from theirs; but it is of a more lively character, and has a more sprightly appearance. They breed and are common in Hudson's Bay, Greenland, Iceland, the Zetland and Orkney Isles, &c. The female makes her nest, which is composed of moss and herbage, lined with a little of her own down, on the very edge of the shore: she lays two eggs, which are somewhat longer than those of a hen, and of a dingy bluish-white, thinly marked with dusky spots. They run swiftly on the surface of the water, but are very awkward on land, from which they rise with difficulty: their flight, however, when once on the wing, is both strong and swift.

THE BLACK-THROATED DIVER (*Colymbus arcticus*) differs in plumage from the last described, and is rather larger. The bill and front of the neck are black; the hind part of the head and neck are cinereous; the sides of the neck are marked with black and white lines, and the fore part is of a glossy variable purple, black, and green. The back, the scapulars, and the coverts of the wings are black; the two former being marked with square, and the latter with round white spots; quills dusky; tail black; legs dark, and reddish on the inside. Like the preceding, this bird is common in all the Arctic regions; and in its winter migrations it visits England, Germany, and Holland. Their skins are dressed, and made into caps, hoods, &c., and are much esteemed as a coverlet for the head and breast in the rigorous climates in which these birds are found, the great thickness of the feathers rendering them very fit for that purpose.

DOBCHICK, or DIDAPPER. (*Podiceps minor*.) A Palmipede bird of the Grebe kind. It seldom exceeds six ounces in weight: the beak is short, large at the base, and tapering to the point: the head is thickly clothed with downy feathers, which it can puff up at pleasure; the eyes are large, the wings small, and it has no tail. Its plumage on the back is of a deep blackish brown colour, and white on the belly. It moves with more facility under the water than on its surface, and raises itself from that element with great difficulty; but when once on the wing, it is capable of continuing its flight for a considerable time. "Ornithologists and sportsmen describe the nest of this bird as being of a large size, and composed of a very great quantity of grass and water-plants, at least a foot in thickness, and so placed in the water that the female hatches her eggs amidst the continual wet, in which they were first laid: and it is conjectured that the natural warmth of her body occasions a fermentation of the herbage, which greatly aids the incubation. She lays from four to six eggs, of a yellowish dull white, and is said to cover them up with the surrounding leaves every time she has occasion to stir abroad." (*Bewick*.)—There are several other species of the Dobchick; as the Horned, the Eared, the Black and White Dobchick, &c.; all of which are larger than the one here described. [See *GREBE*.]

DODO. A large and most unwieldy bird, generally supposed to be extinct, and whose very existence at any period has been doubted. But as there are accounts of it in the works of more than one naturalist, and as it is described most minutely, it behoves us to collect the best information of it we can find. The Dodo is stated to be a native of the Mauritius, or Isle of France; and the Dutch, who first discovered it there, are said to have termed it the nauseous bird, as well from its disgusting figure, as from the disagreeable taste of its flesh. Its appearance, instead of giving one an idea of swiftness, the common attribute of birds in general, seems to strike the imagination as something the most unwieldy and inactive in nature. Its massive and almost globular body, which

is covered in general with grey feathers, is barely supported on two clumsy legs; while its head and neck rise from it in a manner truly grotesque. The neck, thick and puffy in itself, is surmounted by a head composed of two enormous mandibles, opening far behind the eyes, which are large, black, and prominent; so that the huge bird, in gaping,

HEAD AND FOOT OF DODO
(*DIDOS INEPTUS*.)

exhibits a most enormous mouth: hence the bill is of an extraordinary length, thick, sharp at the end, and having each chap crooked in opposite directions; and the two mandibles, which are of a bluish-white colour, in some measure resemble two spoons laid back to back. The Dodo seems to be so weighed down by its own gravity, as scarcely to possess strength sufficient to give energy to its motions; and it appears among the feathered tribe what the Sloth does among quadrupeds, an unresisting creature, equally incapable of flight or defence. Its wings are covered with soft ash-coloured feathers, intermixed with a yellowish-white, but they are too short to render it any essential service in flying: its tail is composed of a few small curled feathers of a light ash-colour; its legs are too short to assist it in running; and its body is exceedingly clumsy. From all that can be gathered concerning this obscurely known bird, it would seem that the species has entirely disappeared; and we now possess no more of it at the present day than a foot preserved in the British Museum, and a head and foot in bad condition at the Ashmolean Museum in Oxford.—Dr. Melville has written, in conjunction with Mr. Strickland, an elaborate memoir on this bird, which they believe to have been a Pigeon somewhat allied to the genus *TACON*. This memoir, or part of it, which embraces the history of the SOLITAIRE, was read at the meeting of the British Association at Oxford, 1847. It has been published, with most exquisitely accurate engravings from the pencils of Ford and Dinkel. In the British Museum there is a painting believed to be a representation of this bird; and in the same case are casts from the Oxford remains, and other casts throwing light on its history. It is a bird which would appear

to have become extinct within the last 200 years. Mr. Duncan, of the Ashmolean Museum, has published an excellent history of all that was known of it up to his time. [See GNATHOPUS: SOLITAIRE.]

DOG. (*Canis familiaris*.) This most faithful and valuable domestic—so remarkable for his incorruptible fidelity, his lasting attachment, his inexhaustible diligence, and his ready obedience—deserves all the eulogies that have been bestowed upon him, and all the kindness that can be shown him, by his master and companion, Man. But independent of his being the most sagacious of all known quadrupeds, and the acknowledged friend of mankind, he is possessed of all those native qualities which contribute to the convenience, and generally conciliate the affections, of the human species. A natural courage and ferocious disposition render the Dog in his savage state a formidable enemy to all other animals: but these qualities speedily yield to very different ones in the domestic Dog, whose only ambition seems to be the desire of pleasing: he approaches with a timid respect, and lays his strength, his courage, and all his useful

NEWFOUNDLAND DOG

talents at the feet of his master; he waits his orders, consults his looks, and a single glance is sufficient to put him in motion. Constant in his affections, and grateful for the slightest favours, he is humble and suppliant under his owner's displeasure, and eventually disarms resentment by unwearied submission. When the care of the house is submitted to him, he appears proud of the charge, and, like a faithful sentinel, he goes his rounds, and gives manifest indications that he is intent on his duty. Thus useful in himself, and being admitted, as it were, to a participation of empire, he exerts a degree of superiority over all other animals which stand in need of human protection. The flocks and herds obey his voice more readily even than that of the shepherd or the herdsman; he conducts them, guards them, confines them within their appointed limits, and considers their enemies as his own. Nor are his arts less serviceable in pursuit, or his unflinching courage less valuable to man, than his personal attachment, his obedient watchfulness, and his patient submission, are endearing.

Cuvier observes that the Dog exhibits "the most singular, the most complete, and the most useful conquest that man has ever made. Every species has become our pro-

perty; each individual is entirely devoted to his master, assumes his manners, distinguishes and defends his property, and remains attached to him even unto death; and all this proceeds neither from mere necessity nor constraint, but solely from true gratitude and real friendship. The swiftness, the strength, and the scent of the Dog have created for man a powerful ally against other animals, and were perhaps necessary to the establishment of society. It is the only animal that has followed man through every region of the earth." What the great French naturalist has here said is strictly true; but every person must agree with Mr. McCulloch, that "it is singular that neither Cuvier, nor any one of those by whom his statements have been copied, should have mentioned that this account is applicable only to Europe. All Mahomedan nations regard the Dog as impure, and will not touch it without an ablution. The same is also the case with the Hindoos. From the Hellespont to the confines of Cochinchina, dogs are unappropriated, and have no master. They prow about the towns and villages; and though they are naturally more familiar, they are in no respect more domesticated, than the carrion crows, kites, vultures, &c. which assist them in performing the functions of scavengers."

If we had sufficient space, and it were necessary to the elucidation of the subject, numerous instances might be cited of the sagacity, affection, courage, generous disposition, and other estimable qualities of this animal, which, if such instances were not well authenticated, would appear incredible; but the universality of such cases renders it almost a matter of certainty that there are few of our readers whose own experience will not furnish them with "anecdotes" of this nature, no less wonderful than true. We shall therefore proceed, without further digression, in an attempt to trace, in the pages of the most eminent naturalists, the source or origin of the species, as far as the intermixture of races or the influence of domestication will permit.

Pennant is of opinion that the original stock of Dogs in the Old World is with great reason supposed to be the jackal; that from their tamed offspring, casually crossed with the wolf and the fox, have arisen the numberless forms and sizes of the canine race. Buffon, with much ingenuity, has traced out a genealogical table of all the known Dogs, deducing all the other varieties from the Shepherd's Dog, variously affected by climate, and other casual circumstances. In the Alpine regions, for instance, this Dog is much larger and stronger than in England. From the recent observations of travellers in the high northern parts of the world, where, although Dogs have been employed for an incalculable length of time, they still retain much of the external appearance and general carriage of a wild animal, it would seem that Pennant's suggestion is worthy of attention. But at the same time it should be remarked, that the breed of Dogs, produced from the wolf and varieties of the domestic dog, during a long succession of generations,

still retains marked characteristics of the predominance of the savage qualities derived from its untamed progenitors, in the keen and vivid expression of the eye, ferocity of disposition, and severity of bite. It is also a singular fact, that the race of European Dogs evince as great an antipathy to the Esquimaux species as they do to a wolf.

In Mr. Bell's History of British Quadrupeds this subject is discussed at considerable length, and with much freedom. "It may not be uninteresting," says our author, "to examine what is the real state of the question, as it regards the original form, from which all the numerous varieties of the Dog have sprung. In order to come to any rational conclusion on this head, it will be necessary to ascertain to what type the animal approaches most nearly, after having for many successive generations existed in a wild state, removed from the influence of domestication, and of association with mankind. Now we find that there are several different instances of the existence of Dogs in such a state of wildness as to have lost even that common character of domestication, variety of colour and marking. Of these, two very remarkable ones are the Holo of India, and the Dingo of Australia; there is, besides, a half-reclaimed race amongst the Indians of North America, and another, also partially tamed, in South America, which deserve attention: and it is found that these races, in different degrees, and in a greater degree as they are more wild, exhibit the lank and gaunt form, the lengthened limbs, the long and slender muzzle, and the great comparative strength which characterize the Wolf; and that the tail of the Australian Dog, which may be considered as the most remote from domestication, assumes the slightly bushy form of that animal.

"We have here, then, a considerable approximation to a well-known wild animal of the same genus, in races which, though doubtless descended from domesticated ancestors, have gradually assumed the wild condition; and it is worthy of especial remark, that the anatomy of the Wolf, and its osteology in particular, does not differ from the dogs in general, more than the different kinds of dogs do from each other. The cranium is absolutely similar, and so are all, or nearly all, the other essential parts; and to strengthen still further the probability of their identity, the Dog and Wolf will readily breed together, and their progeny is fertile. The obliquity in the position of the eyes in the Wolf is one of the characters in which it differs from the Dogs; and although it is very desirable not to rest too much upon the effects of habit or structure, it is not perhaps straining the point, to attribute the forward direction of the eyes in the Dogs, to the constant habit, for many successive generations, of looking forward to their master, and obeying his voice.

"A point of very considerable importance in the question of the identity of species is the period of gestation. This circumstance is so invariable in individuals of the same

species, and so rarely the same in those which are distinct, however nearly they may be allied, that if, in this respect, two animals be found to differ, it would be a strong ground for doubting at least, perhaps even for rejecting, the opinion of their identity; and, on the other hand, their absolute coincidence on this point would afford a collateral argument of equal force in its favour. Buffon indeed relates an instance of the Wolf, in which the period might possibly have been seventy-three days; but even on

GREYHOUND

his own showing, it might have been no more than sixty-three; and certain circumstances detailed in the account afford strong reason for believing this to have been the case. Hunter, who instituted a series of interesting and, as far as they went, important experiments, in order to ascertain whether the Wolf and the Jackal would respectively breed with the Dog, comes to the conclusion, on finding the affirmative to be true in both instances, that the Dog, the Wolf, and the Jackal are of one species. But he found that the period of the Jackal is fifty-nine days, whilst that of the Wolf is sixty-three days, the same as that of the common Dog. Desmarest also gives sixty-three days as the period of the Wolf. As far as this character goes, therefore, it is in favour of the identity of the Wolf and Dog, and of the specific distinctness of the Jackal. The conclusion which Hunter draws from the fact that each of these wild animals will breed with the Dog, and produce young which are fertile again with the Dog, is, however, not yet satisfactory; and the argument would be much stronger were it proved that the progeny would breed with each other, which has not at present been done. It appears that in many other cases, especially amongst birds, the hybrids will breed with either of the parent species; but the more satisfactory experiment just proposed remains to be tried; and until this has been done, the chain of evidence is incomplete, and the validity of the argument derived from the alleged fertility of progeny is inconclusive." [Our author here details some striking facts to prove that the supposed untamable ferocity of the Wolf may not merely be subdued, but that he may become truly attached and friendly to those who treat him with kindness.]

"Upon the whole, the argument in favour of the view which I have taken, that the Wolf is *probably* the originator of all the

canine races, may be thus stated:—The structure of the animal is identical, or so nearly so, as to afford the strongest *a priori* evidence in its favour. The Dog must have been derived from an animal susceptible of the highest degree of domestication, and capable of great affection for mankind; which has been abundantly proved of the Wolf. Dogs having returned to a wild state, and continued in that condition through many successive generations, exhibit characters which approximate more and more to those of the Wolf, in proportion as the influence of domestication ceases to act. The two animals will breed together, and produce fertile young. The period of gestation is the same.

"The races of Dogs have at different times been variously classified, according to the views of the respective authors; but, as it appears to me, with very little truth in a zoological point of view, and as little practical advantage. Although it is obvious that certain varieties approach more nearly to each other in habit and conformation than others, there is not sufficient ground for a regular systematic arrangement. Buffon, F. Cuvier, and other authors, have attempted such classifications; but they have been merely artificial, and in many instances have gone upon erroneous suppositions as to the origin of mixed races.

"The food of the Dog is various. It will live on cooked vegetable matters, but prefers animal food, and is particularly fond of it when approaching putrefaction. Its stomach will digest portions of bone. In drinking, it laps with the tongue; it never perspires; but the nose is naked and moist; and when hot, the tongue hangs out of the mouth, and a considerable quantity of water drops from it. It walks round the place it is about to lie down upon, and coils itself up in the same direction. The female goes with young sixty-three days, and usually has about six or eight at a litter; though sometimes as many as twelve or fourteen. These are blind at birth, and do not acquire their sight until the tenth day. It is commonly stated that the male puppies resemble the father, and the female the mother: this, however, if it be true to a certain extent, is not absolutely so; but, like many other animals, the father of the first litter often pro-

quire repetition. Those which belong to the different races will be briefly mentioned under the separate heads."

Like the young of most animals which bring forth many at a time, the Dog is not perfectly formed when first produced. During their blind state the bones of their skulls are incomplete, their bodies are inflated, their noses are contracted, and their whole figure is but imperfectly represented; but in less than a month the puppy begins to acquire all its senses, and from that time makes hasty advances to perfection. At the end of the fourth month, the Dog, like other animals, sheds some of his teeth, which are renewed by such as are permanent. The teeth of the Dog being his principal, and indeed his only defence, they are formed in such a manner as to render him the most essential services: he cuts with his incisors or fore-teeth; he holds with his four great canine ones; and he chews with his grinders, which are fourteen in number, and so placed that when his jaws are shut there remains a distance between them; so that on opening his mouth to the greatest possible stretch, he does not lose the power of his jaws. Though the Dog is a voracious animal, he is capable of enduring hunger for a considerable length of time: it seems, indeed, that water is more necessary to his subsistence than food; and he drinks often, though not abundantly.

We shall conclude this article with some extracts from an ingenious essay "On the Dog, as the Companion of Man in his Geographical Distribution," by Dr. T. Hodgkin, in *The Zoologist*, edited by Mr. Newman:—"The most striking natural group, the most marked in its characters, and the most widely diffused of all the known varieties, is that which we may trace from China, over the northern portion of the old continent, to the islands of the Northern Ocean and the northern part of America. In this wide extent we find, as we should reasonably anticipate, some distinctly marked subdivisions, yet all so evidently maintaining the common type, that the least skilful observer must immediately recognize the family resemblance. The dogs constituting this group may be thus enumerated: 1. Those of China. 2. Those of Kamskatka, and others of the same stock employed in drawing sledges in the northern parts of Asiatic Russia. 3. The very distinctly marked variety of dogs occurring in the northern parts of Europe, and which are called *Spitz* in Germany, but which are known as Pomeranian dogs when introduced into France and England. 4. The dogs of Iceland, with which are probably connected those of Lapland and Greenland. And lastly, those of the Esquimaux. A very remarkable family likeness is to be detected in all this group, of which perhaps the most striking features are the sharpened nose, rather small pointed ears, the approaching eyes but little projecting, the superior length of hair about the neck, with a greater or less tendency to shagginess on the other parts of the body, and, in most instances, an elevated curled tail, with a temper which may be characterized as restless and irritable. We meet with many va-

SHEPHERD'S DOG.

needs an impression which is scarcely lost in all the subsequent ones. This is a fact worthy of particular attention, as it bears upon a question of as great interest and importance as any in the whole range of animal physiology. Such are some of the general habits of the whole species: and there are many others which are too well known to

rieties in stature, colour, and length of hair. Thus it would appear that the dogs of China are often black, the epitelium of the mouth and tongue having the same colour. Those of the north of Europe are almost invariably white or light brown, whilst those of the Esquimaux are often black and white. From China we see specimens both of large and of small size, having the same characteristic form. Those of the Esquimaux and Kamskatkadales are of rather a large size,

whilst those of Iceland are small, and probably lower in proportion than any other of the group. The dogs of this group appear to differ as widely in their degree of fidelity and docility. The Pomeranian variety, which is perhaps the most completely domesticated, is faithful and sagacious, and makes an excellent guard, and the smaller specimens become the admired pets of the ladies. From an example which came to my knowledge, I am inclined to believe that the Chinese dogs have the same character. Those of the Esquimaux and the Kamskatkadales are chiefly valuable on account of their strength and endurance of fatigue; but they are often ill-tempered and untractable; and though decidedly sagacious and capable of being trained as retrievers, they are destructive, and cannot be left with safety in the way of live stock, bearing in this, as well as in some other particulars, a strong resemblance to the wolf, with which it is known that their blood is occasionally blended. It may, however, be observed, that independently of such known connexion, the whole group of which we are now speaking has something more of the wolfish expression than any other variety of the *Canis familiaris*. * * *

"Another extensive division of the species, and which appears to me to have been spread over a different portion of the globe, and probably to belong to the western part of Asia, the southern parts of Europe, and north of Africa, may perhaps be regarded as comprising the true hunting dogs. They possess, for the most part, well-developed noses; their ears are large, broad, and pendulous; their proportions rather thick than otherwise; their jaws large as compared with other dogs, and their tails thick. The descriptions of hounds left by Greek authors, seem to have been applied to dogs of this stock, which will also be recognized in the old English hound, and in all the varieties of the modern hound, down to the bangle. The pointer strikingly exhibits the same characters, and all the varieties of spaniel appear to be essentially branches of the same

family, though probably modified by a cross, respecting which I shall presently hazard a conjecture. The true smooth terrier appears to be of the same division, though some passing under this name are probably mixed with another stock. In some of the dogs of this group we find probably the most marked effects of culture. Their large pendulous ears, as in some varieties of rabbits, may be referred to this cause. With a greater degree of submission and attention to man, they have also a greater degree of dependence upon him, and some almost resemble the sheep and the cow in this respect, whilst their more artificial faculties, which have been cultivated for many generations, have become innate in the offspring. Thus the pointer's puppy, of a few weeks old, begins to point of his own accord, and anticipates the first lessons of his trainer; just as young horses will frequently adopt the artificial paces which have been taught to their sires.

"A third group is less distinctly marked as a whole, and I am not prepared to lay any great stress on the reasons which have induced me to bring some of its varieties together; but in others we have the strongest evidence of their affinity, both in visible characters and known connection of blood, notwithstanding great apparent differences of figure. In this group I would place the greyhound, and that variety of shepherd's dog which most nearly approaches him in form. It would be quite a mistake to suppose that the shepherd's dog is a single variety, since different kinds of dogs are employed for this purpose in different districts. The transition of the greyhound to one of the shepherd's dogs takes place by almost insensible degrees, and Cowper's description of half lurcher and half cur must be familiar and graphic to almost every one. In the young animals, when no mutilation of the tail has taken place, the resemblance is most striking. Another variety, perhaps, is more related to the greyhound than even any variety of shepherd's dog; I mean the English bull-dog. It was the perception of the striking resemblance in some points exhibited in these animals, notwithstanding their general difference of figure, before I was aware of the actual consanguinity which breeders are careful to maintain, which first led me to notice the indications of a natural grouping which would seem to clash with artificial arrangement. Though the bull-dog is short, compact, and heavy, with a proverbially large blunt head and broad face, and the greyhound is the very emblem of lightness, his elongated nose, head, and neck resembling a snake, his back long, curved, and flexible, his body, which, with sufficient room for the organs of circulation and respiration, affords almost none for those of digestion, and supported on long and slender limbs, which seem to render him among quadrupeds what the *hirondelle de mer* is among birds—there are individual points of resemblance between the two dogs which are perhaps more striking than any which can be found among other varieties. The feet and toes are remarkably delicately formed; the ears small and pointed,

though generally inclined to be pendulous, capable of being erected; the tail remarkably slender, some of the stoutest bull-dogs having tails which would grace an Italian greyhound. Similar colours also prevail in both varieties, and more especially the brindled, the mottled, and the more or less white. In both, the sense of smell is slow for the dog, whilst the sight is good. Both are ferocious and savage when set on: the ferocity of the greyhound is not unfrequently shown in the destruction of sheep."

The author then gives reasons for presuming that the Newfoundland dog, which he says has been regarded as a large species of water-spaniel, is distinctly traceable to the Esquimaux stock; and he concludes by observing that whatever may be the value and results of inquiries like these, as respects the study of ethnology, the labour need not be in vain as respects the animals themselves, since conclusions of more or less practical value can scarcely fail to be deduced for the guidance of the breeder and the benefit of the public.

Dogs are found in all parts of the world, with the exception of a few groups of islands in the Southern Pacific Ocean. But it is only in temperate climates that they preserve their ardour, courage, sagacity, and other talents. (See BLOODHOUND, BULL-DOG, FOXHOUND, GREYHOUND, HOUND, MASTIFF, POINTER, SPANIEL, SHEPHERD'S DOG, &c.)

DOG-FISH. (*Scyllium catulus*.) This species of Shark, called the Large-spotted Dog-fish, is from two to three feet in length; the head is large; the snout prominent and slightly pointed; the skin rough; body cylindric; the colour a brownish grey, with a slight tinge of pale brick red, and marked with very numerous blackish or dusky spots; the belly whitish, and very smooth. These fish, when at their full growth, weigh about twenty pounds each: they are caught in considerable numbers on our own coasts, where their voracious habits do great injury to the fisheries; and in Scotland they constitute no inconsiderable part of the food of the poor. The rough skin of this fish is used by joiners and other artificers in polishing various substances, particularly wood, and is generally known by the name of "fish-skin."

The **SMALL-SPOTTED DOG-FISH** (*Scyllium canicula*) is in many respects similar to the preceding, and is one of the most common species on our southern coasts, where, keeping near the bottom of the water, it feeds on small fish and crustacea. The upper part of the body is marked with numerous small, dark, reddish-brown spots, on a pale reddish ground; the spots on the fins rather larger and less numerous than those on the body.

The **PICKED DOG-FISH** (*Spinax acanthias*) is a species very common on the coasts of Kent and Sussex, where it is almost universally called the Bone Dog; it is also very numerous on the north-eastern and western coasts, and is often seen in shoals among the Scotch islands. This fish is distinguished from

the others of this class by having a single spine placed in front of each of its two dorsal fins, and from which it derives its name. We learn from Mr. Yarrell, who quotes Mr. Couch, that "they are sometimes found in incalculable numbers, to the no small annoyance of the fishermen, whose hooks they cut from the lines in a rapid succession. The Picked Dog bends itself into the form of a bow for the purpose of using its spines, and by a sudden motion causes them to spring asunder in opposite directions; and so accurately is this intention effected, that if a finger be placed on its head, it will strike it without piercing its own skin." Length about twenty inches; the upper part of the head and body slate grey; under parts yellowish.

Another species, called the **BLACK-MOUTHED DOO-FISH**, (from the colour of the inside of its mouth) is well known in the Mediterranean. It runs from two feet to two feet six inches in length; is of a light brown colour on the head and along the back, and on each side are two rows of ocellated spots.

DOLABELLA. A genus of Tectibranchiate Mollusca, closely allied to the *Scapharæ* (*Aplysia*), differing from them in having the branchiæ at the posterior part of the body, which looks like a truncated

DOLABELLA RUMPHII AND INNER SHELL.

cone. Their lateral crest does not close on branchiæ, leaving a groove. The innershell is calcareous. There is more than one species; the genus is found both in the Mediterranean and the Eastern seas. Interesting observations on them and allied genera have been recorded by A. Adams, F.L.S.

DOLICHOSAURUS. [See SUPPLEMENT.]

DOLIUM. A genus of Mollusca, inhabiting univalve shells, found, for the most part, in the Indian, African, and South American

PARTRIDGE SEZIL. — (DOLIUM PERDIX)

seas: the shell is large, light, and oval or globular; the mouth wide and notched,

generally transversely banded. The molluscous animal contained in it has a large head with short proboscis, and two tentacula with eyes in the middle. There are several species, most of which may be seen in the fine collection at the British Museum. The foregoing figure of the Partridge Shell (*Dolium perdix*) will give a very good general idea of the form of this genus.

DOLPHIN. (*Delphinus delphis*.) This cetaceous animal bears a great resemblance to the Porpoise, but has a much longer and sharper snout, and the body is of a more slender shape. It often grows to the length of eight or ten feet; the colour on the back and sides is dusky, and the belly whitish; the teeth are very numerous, sharp pointed, and slightly bending forwards; and they are placed so close together, that when the mouth is shut the jaws lock into each other. The Dolphin is found in the Mediterranean and Indian seas, and seems to be generally confounded by navigators with the Porpoise, having the general manners and appearance of that animal. It swims very swiftly, and preys on various kinds of fish; and it sometimes happens that either from its impetuosity in the pursuit of prey, or the calls of hunger, it is urged beyond the limits of safety; and the fishermen on the Cornish coasts, who spread their extensive nets for pilchards, sometimes become possessed of a very unwelcome prize.

By ancient writers the Dolphin was celebrated for its supposed affection for the human race, and its appearance was regarded as a favourable omen. Numerous, indeed, are the fables of antiquity in this respect, which could have no better foundation than poetic fiction: its figure is far from prejudicing us in its favour; and its extreme rapacity tends still less to endear it to us.

COMMON DOLPHIN.
(*DELPHINUS DELPHIS*.)

The prejudices of the moderns are of a contrary character; for the appearance both of this species and the porpoise in sea, is generally considered as one of the preludes of an approaching storm. Dolphins inhabit every sea, from the equator to the poles, enduring equally well the extremes of heat and cold. The Dolphin, respiring by lungs, and not in the manner of fishes, is compelled to rise to the surface to breathe, throwing out the water from the blow-hole, or aperture in the head, like a cloud of steam. This hole is of a semilunar form, with a kind of valvular apparatus, and opens nearly over the eyes. The structure of the ear renders the sense of hearing very acute, and the animal is observed to be attracted by regular or harmonious sounds. Compactness and strength are the characteristics of the genus, and the mus-

cular powers of the tail are proverbial. The Dolphin is said to be long-lived, and, like the Whale, seldom brings forth more than one young one at a time, which the parent suckles and watches with great care and anxiety.

It is, perhaps, almost unnecessary to caution the reader not to confound the cetaceous species we have been describing, with the fish commonly known as the Dolphin at the present day, and hereunder described.

DOLPHIN. (*Coryphæna hippuris*.) This Acanthopterygious fish has a flat and roundish snout, and the body tapers from the head to the tail; but its principal beauty consists in the brilliancy of its colours. The back is

DOLPHIN.—(*CORYPHÆNA HIPPURIS*)

spangled with bright bluish-green spots; the tail and fins are of a gold colour; and whether viewed alive in its native element, or before it is quite dead, nothing can surpass its lustre. It is about five or six feet long, and nearly as thick as the salmon. A remarkable fin runs from the head, along the back, to the root of the tail, which in the middle is seven inches broad, and consists of a kind of coriaceous membrane with soft spines; opposite to which there is another fin, not more than an inch broad, and extending from the vent to the tail. The tail, which is upwards of two feet and a half long, is divided into two large horns; and the scales are so very minute as to be hardly perceptible. This fish swims with such amazing velocity, as frequently to keep pace with a swift sailing ship for a very considerable time. They abound within the tropics, and are found in all temperate latitudes. In the neighbourhood of the equator, they commit great havoc in the immense shoals of flying-fish which inhabit those regions, and which constitute the principal food of the *Coryphæna*. It is remarkable that, in swallowing their prey, the position of the captured fish is reversed, and it passes down the throat head foremost; by which manœuvre the fins are prevented from impeding the passage.

DONAX. A genus of bivalve shells, the form of which is inequilateral and wedge-shaped. It is found in all parts of the world buried in the sand of the sea-shore. Many of the species are beautiful; but only two, it is said, are found on the British coasts; one called the Yellow Donax, the other the Purple.

DORIPPE. A genus of brachyurous Decapod Crustaceans (comprehended under the general term *Cancer* by Linnaeus), found on the sea-coasts of warm climates, where the water is deep; the Mediterranean and Adriatic seas being among the localities given.

They are generically characterized by having rather long external antennæ, inserted above

FLAT-FRONTED DORIPPE.—(DORIPPE SIMA.)

the intermediate ones, which are folded, but not entirely lodged in the cavities where they take their insertion: claws (*chela*) small, short, equal; the other feet very long and compressed, the third pair being the greatest; the two last pair elevated upon the back, and terminated by a small hooked nail: carapace slightly depressed, truncated, and spinous before; truncated, sinuous, and bordered behind; the surface marked with small humps or tubercles: inferior and posterior part of the body truncated into a kind of gutter to receive the reflected abdomen, the pieces of which are tuberculous. The eyes are small, lateral, and supported on moderately long peduncles. It is now known, from Mr. Cuming's observations appended to a specimen in the British Museum, that they make use of the feet, elevated on the back to cover themselves, like the *Dromia*, with foreign bodies. There are some fossil as well as recent species. One fossil species, brought from New Holland by Peron, is named *Dorippe nodosa*. In the fine collection of James Scott Bowerbank, F.R.S., there are specimens of a species of this genus found on the Isle of Sheppey, in the London clay.

DORIS. A genus of naked Gasteropodous marine Mollusca, which are likewise destitute of any internal testaceous plate. The mantle is covered with retractile papillæ, and separated from the foot by a distinct duplicature. Towards its anterior margin are placed the two superior tentacula: these are retractile, surrounded at the base with a short sheath, and supported on a slender stem, having an enlarged compound plicated

THE OOROEIOUS DORIS.—(DORIS MACULATA.)

summit. The neck is short, and above the mouth there is a small projecting membrane connected at each side with the oral tentacula, which are in general minute, and of difficult detection. The mouth is in the form of a short trunk, leading to fleshy lips, within which the tongue is placed. The gullet is a simple membranaceous tube, terminating in a stomach. It is obvious, from the structure of the digestive organs, that the species subsist on soft food. The spawn is gelatinous and of a white colour, and is deposited on sea-weed and stones.

Messrs. Alder and Hancock are publishing

in one of the works of the Ray Society, descriptions and figures of all the British species of Doris and allied genera, forming the Nudibranchiate Mollusca. It is a truly elegant work, the illustrations in which must arrest the attention of even those who feel but little interest in the subject. Col. Montagu, Dr. Johnston of Berwick, and Messrs. Alder and Hancock, with other naturalists, have shown how rich our own coasts are in these beautifully organized shell-less mollusca.

DORMOUSE. (*Myoxus*.) A genus of mammiferous quadrupeds, of the Linnean order *Glires*. They appear to be intermediate between the squirrels and mice; inhabit temperate and warm countries, and subsist entirely on vegetable food. They have two cutting teeth in each jaw; four toes before, and five behind; and naked ears. These mice inhabit woods and thick hedges, building their nests, which are lined with moss and dead leaves, either in the hollows of trees, or near the roots of close shrubs. Towards the approach of winter they form little magazines of nuts, beans, acorns, &c., on which to subsist during the inclement season; when they retire to their retreats, roll themselves up, and fall into a torpid or lethargic state, which lasts, with little interruption, till the winter is over. It was formerly believed that their hibernation was a state of continual sleep from the period that they sought their winter quarters until they emerged from them in a more genial season. But, however, very properly exposed the absurdity of the ancient notion; and has observed that these animals occasionally wake, and make use of their stock of provision. They bring forth three or four at a time, which are usually born blind, and remain so for a few days. There are several species.

THE COMMON DORMOUSE. (*Myoxus avellanus*.) The body is about the size of that of the common mouse, but it is of a more plump or rounder form, and the nose is more obtuse: the eyes are large, black, and pro-

COMMON DORMOUSE.
(MYOXUS AVELLANUS.)

minent; the ears round and semi-transparent; the tail is two inches and a half long, and more hairy towards the tip than on the other parts: the head, back, sides, belly, and tail are of a tawny red colour, but the throat is white: the fur is remarkably soft, and the animal altogether has a

considerable degree of elegance in its appearance. Its habits are similar to those described in the preceding paragraph.

THE FAT DORMOUSE. (*Myoxus glis*.) This species is a native of France and the South of Europe. Its body is covered with soft ash-coloured fur; the belly is whitish; the tail is surrounded with very long hair; and the ears are thin and naked. Its length, from the nose to the tail, is nearly six inches, that of the tail being four and a half; and the body is thicker than a squirrel's. Like the last-mentioned animal, although these have not its activity and sprightliness, they can ascend trees in search of their food, which they carefully store up for their winter consumption. During its state of torpidity it is said to grow very fat, contrary to the nature of most of the hibernating or sleeping animals; but there is no doubt that it occasionally wakes, and feeds on its store; in truth, it is at all times fat, and appears as much so in spring as in autumn. Its flesh was esteemed a great delicacy by the Romans, who had their *gliraria*, or places in which they were kept and fattened for the table.

THE GARDEN DORMOUSE (*Myoxus nitela*) is a native of the temperate parts of Europe and Asia. It makes its nest, like the rest of this genus, in the hollows of trees, and sometimes in those of walls, where it generally fixes its abode, and remains in a state of torpidity during a great part of the winter, awaking, however, at intervals. Its general length is about four inches and a half, and the tail not quite so much. It is of an elegant rufous colour above, and yellowish white underneath: the eyes are imbedded in a large black patch or spot, which extends to some distance beyond each ear: the tail is rather wide towards the end, sharpening at the extremity, and is marked on that part by a longitudinal black stripe, having the edges white. Delighting in all sorts of fruit, but particularly in wall fruit, these animals prove very destructive in gardens. They produce their young about the middle of summer, which are about five or six in number.

DORSIBRANCHIATA. A name given by Cuvier to an order of *Annelidae*, or red-blooded worms, which have their organs, and particularly their gills, distributed about equally throughout the middle part of the body. The *Nereis*, or *Scen-centipede*, is an example of this order. [See *NEREIDA*.]

DORY, DOREE, or JOHN DORY. (*Zeus*.) There are several species of this very singular Acanthopterygious fish, which is distinguished by having the spinous portions of the dorsal and anal fins separated by a deep emargination from the soft-rayed portion, and having the base of all the vertical fins, and the carina of the belly anterior to the anal fin, furnished with spines.

The **COMMON DORY** (*Zeus faber*) is a native of the Mediterranean, Northern, and Atlantic seas; but no locality is more noted for it than Torbay, on our own western

coast. It is distinguished by its large and long head, its dusky green colour, accompanied by a strong gilt tinge, and particularly by a large, oval dusky spot on each

DORY - (ZEUS FABER.)

side the body: the mouth is wide, the lower jaw longer than the upper, the teeth small and sharp, and the eyes large; the whole body is covered with very small scales, and marked by a curved lateral line, which, descending rather suddenly from the gill-covers, passes on to the tail: the back is much arched, and furnished with a row of strong small prickles, which are also continued along the curve of the abdomen: the tail is of a moderate size, and rounded at the end. The Dory is of an extremely voracious nature, preying on the smaller fishes and their spawn, as well as on various kinds of crustacea and marine insects. The form of the Dory is extremely forbidding, so much so as to deter our ancestors from tasting it; and although its flesh is now esteemed delicious food, its reputation among epicures is but of modern date. The name is said to be derived from the French, *jaune* (yellow) *dorée*, corrupted into John Dory. In general it is from twelve to fifteen inches in length, though it sometimes arrives at a far superior size, and of the weight of ten or twelve pounds.

There are a few other species, but less remarkable than the preceding:—The **BRAZILIAN DORY** (*Zeus romer*), which is about six or eight inches long; body very thin, without scales, and of a bright silver colour, tinged with a bluish cast on the upper parts.—The **INDIAN DORY** (*Zeus Gallus*) is about the same size as the one just mentioned: body very thin, silvery, and without scales: head large, mouth wide. Native of the American and Indian seas.—**CILIATED DORY.** (*Zeus Ciliaris*.) This species, which is also destitute of scales, is of a bright silver colour, with a cast of bluish-green on the back: head small, and very sloping; lower jaw rather longer than the upper: several of the last rays both of the dorsal and anal fin extend to a vast distance beyond the membrane, reaching farther than the tail itself. It has been supposed that the smaller kind of fishes may be attracted with these long and flexible filaments, and mistake them

for worms, while the Dory lies concealed among sea-weeds, &c., waiting for its prey. It is a native of the Indian seas. [See ZEUS.]

DOTTEREL. (*Charadrius morinellus*.) This Gallatorial bird is about ten inches in length: the beak black, slender, and one inch long: forehead mottled with dusky and grey; the hinder part of the head is black; and a broad white line over the eyes surrounds the whole. The back and wings are a light brown; the breast is a pale dull orange; the middle of the belly is black: the edges of the feathers are pale rust colour, and the lower part of the back and rump incline to gray. The tail is composed of twelve brown olive-coloured feathers, barred with black near the ends, and tipped with white: the thighs are a reddish white, and the legs black. The female is rather larger, and the colours more dull; the white line over the eye is smaller; and the crown of the head is mottled with brown and white. Dotterels inhabit the northern parts of Asia and Europe, frequenting the muddy borders of rivers: they are migratory, being seen on our moors and downs in their flights to and from their breeding-places, from April to June, and again from September to November. Being fresh from regions and wilds untrod by man, and not having experienced persecution, they do not so readily take alarm, as other birds do which have been reared in the vicinity of their general enemy: they have, in consequence, obtained the character of being very stupid birds, and, it is said, may be taken by the most simple artifice; but night-fowling, and all modes of ensnaring them, have yielded to the more certain method of bring them down with a gun.

DOTTEREL, SEA. [See TURNSTONE.]

DOVE. [See PIGEON: RING-DOVE: TURTLE-DOVE.]

DRAGON. (*Draco volans*.) Instead of the formidable monster of this name, which recalls to the imagination the wild fictions of romance, the animal we are about to describe is a small and harmless lizard, agreeing in the general form of its body with the rest of that tribe; but furnished with large, expansile, cutaneous processes, which, when expanded, enable it to support itself in the air for a few seconds, in springing from branch to branch, among the lofty trees in which it resides. The total length of this highly curious creature is about ten or twelve inches: the tail being extremely long in proportion to the body, which is not above four inches. The head is of a moderate size, but very singular form, being furnished beneath with a very large triple pouch, one part of which descends beneath the throat, while the two remaining parts project on each side; all being sharp-pointed: the mouth is rather wide; the tongue large, and thick at the base; the teeth small and numerous; the neck, body, and limbs rather slender, and covered with small acuminate and closely-set scales. The colour of this animal on the upper parts is an elegant pale

blue, or bluish-grey, the back and tail being marked by several transverse dusky undulations, while the wings are very elegantly spotted with patches of black, brown, and

DRAGON.—(*DRACO FIMBRIATUS*.)

white: the border of the wings is also white, and the whole under surface of the animal is of a very pale or whitish brown colour. Species of this genus are inhabitants of many parts of Asia, Africa, and South America; they feed on insects; and are in every respect animals of a harmless nature.

All the frightful animals described and figured in the works of some of the older naturalists, under the name of Dragons, are merely fictitious beings, either artificially composed of the skins of different animals, or made by warping some particular species of the ray or skate tribe into a dragon-like shape, by expanding and drying the fins in an elevated position, adding the legs of birds, &c., and otherwise disguising the animals. Such also are the monstrous representations (to be found in Gesner and Aldrovandus) of a seven-headed Dragon, with gaping mouths, long body, snake-like necks and tail, and feet resembling those of birds. Some of the dragons of antiquity are described as having no feet, but as crawling like serpents, and their bodies covered with scales, and so powerful as to crush an elephant with the greatest ease. The animal which gave rise to these is probably no other than the great Boa Constrictor. Again, who has not heard of the fabled Dragon of the middle ages, which had the feet of a lion, the long thick tail of a serpent, and an immense throat, from which streamed flames of fire? This dragon played a distinguished part in the days of chivalry; and was one of those monsters whom it was the business of the heroes of romance to attack and destroy. We have, involuntarily as it were, been led to notice the fabulous history of the Dragon, in order to point out the gross absurdities connected with Natural History, which, though long since exploded, were at one period received as matters of fact.

DOUG. (*Sarunopithecus*.) A genus of Monkeys peculiar to Cochin China, the East Indies, and neighbouring islands. They

differ from the true Monkeys by having an additional small tubercle on the last of the inferior molars; and are farther distinguished by their lengthened limbs and extremely elongated tail. In their muzzle, as well as in having posterior callosities, they resemble the Gibbons. Though capable of much agility, their movements are staid and deliberate, and their general deportment remarkable for gravity. [See MONKEYS.]

DRAB [MOTHS]. A name given by collectors to Moths of the genus *Orthona*. They are also called **QUAKERS**.

DRAGONET. (*Callionymus lyra*.) A beautiful Acanthopterygious fish, inhabiting the Mediterranean and Northern seas, and about a foot in length. The head is large and somewhat depressed; the mouth wide, and the teeth small and numerous; the eyes are placed near each other on the upper part of the head; the body is of a taper form, smooth, and destitute of visible scales. According to Pennant, the pupils of the eyes are of a rich sapphire blue colour; the fringes fine fiery caruncle, the pectoral fins light brown; the side lines straight; the colours of the fish yellow, blue, and white, making a beautiful appearance when fresh taken.

There are two or three other species, one of which, called the **OCCELLATED DRAGONET**, (*Callionymus ocellatus*) about the size of one's little finger, is a native of the Indian seas. The head is smaller and sharper than in others of the genus, and rather flat at the top; mouth small, with tumid, fleshy lips; the upper one doubled; lateral line straight; tail rounded.

DRAGON-FLY. (*Libellulidæ*). A numerous family of Neuroptera. They are of blue, green, white, crimson, and scarlet colours; in some a variety of the most vivid tints are united; and they are easily distinguished from all other insects by the length of their bodies, the large size of their eyes, and the beautiful transparency of their wings. These

DRAGON FLY.—(*ÆSHNA GRANDIS*.)

brilliant and lively insects, which are seen flying with such strength and rapidity round the meadows, and pursuing the smaller insects with the velocity of a hawk, were at one time inhabitants of the water, and resided in that element for a long space of time before they assumed their flying form.

The mouth of the Dragon-fly contains a formidable apparatus of mandibles and maxillæ, denticulated at the tip; the antennæ are very short, being merely a pair of small hairs; the wings large and spreading, and the body elongated.

There are many different genera and species of the *Libellulidæ*, both native and exotic. One of the largest English species is the *Æshna varia*, or Great variegated Dragon-fly. This insect makes its appearance principally towards the decline of summer, and is singularly elegant; its general length is about three inches from head to tail, and the wings when expanded measure near four inches from tip to tip; the head is very large; the neck extremely slender; and the eyes, which occupy by far the greatest part of the head, are of a pearly blue-gray cast; the front is greenish yellow; the thorax of the same colour, but marked by longitudinal black streaks; the body, which is very long, slender, and sub-cylindrical, is black, richly variegated with bright blue and deep grass-green: the wings are perfectly transparent, strengthened by very numerous black reticular fibres, and exhibit a strongly iridescent appearance. In the day-time it flies about in pursuit of its prey with astonishing rapidity; but during the early morning hours, and in the evening, it is observed to sit with its wings expanded, and may be easily taken.

All the insects of this family are produced from eggs deposited in the water, which, sinking to the bottom, are hatched, after a certain period, into flatfish hexapod larvæ: they cast their skins several times before they arrive at their full size, and are of a dusky brown colour: the rudiments of the future wings appear on the back of such as are advanced to the pupa or chrysalis state, in the form of a pair of oblong scales; and the head is armed with a most singular organ for seizing its prey; viz., a kind of flat proboscis, with a joint in the middle, and a pair of strong hooks or prongs at the end. This proboscis, when the Dragon-fly is at rest, is folded or turned up in such a manner as to lap over the face like a mask; but when the creature sees any insect which it means to attack, it springs suddenly forwards, and by stretching forth the jointed proboscis, readily obtains its prey. In this their larva and pupa state they continue for two years, when, having attained their full size, they prepare for their ultimate change; and creeping up the stem of some water-plant, and grasping it with their feet, they make an effort by which the skin of the back and head is forced open, and the enclosed *Libellula* gradually emerges, its head and wings first appearing. The wings, at this early period of exclusion, are very tender and contracted, all the ramifications or fibres having been compressed within the small compass of the oblong scales on the back of the pupa; but in about half an hour they are fully expanded, and have acquired the strength and solidity necessary for flight. This curious process of the evolution or birth of the Dragon-fly generally takes place on a fine sunny morning; and though for a

time it roves the field and forest, or disports itself on the margin of the silvery stream—lightly traversing the air in a thousand directions, and expanding its gossamer wings to the sun—how short is its aerial and terrestrial life, compared with that which it passed in its aquatic state! Scarcely have the frosts of autumn nipped the tenderest plant, ere the whole tribe of Libellulæ perish from the cold.

Among the varieties of the Dragon-fly, many of them may sometimes be observed in the same field, or flying within a small distance of each other on the borders of their natal stream; and though they differ in their size and variegations, their general form and habits correspond too nearly to be mistaken for any other winged insects. A specific notice of each may therefore be thought unnecessary. We shall, however, avail ourselves of Dr. Shaw's description of one species of "exotic" Libellula, and his concluding remarks relative to the extraordinary character of the eyes of these insects in general. "The *Libellula Lucretia* is a native of the Cape of Good Hope (or rather of S. America), and is distinguished by the excessive length of its slender body, which measures not less than five inches and a half in length, though scarcely exceeding the tenth of an inch in diameter: the wings are transparent, of a slender or narrow shape, as in the *L. puella*, to which this species is allied in form, and measures five inches and a half in extent from tip to tip: the colour of the head and thorax is brown, with a yellowish stripe on each side, and the body is of a deep mazarine blue.

"I should not dismiss the genus *Libellula* without observing that in some species, and particularly in the *L. varia*, *grandis*, &c., the wonderful structure of the cornea or external coat of the eye, which prevails in by far the major part of the insect tribe, is exhibited with peculiar distinctness. Even a common magnifier, of about an inch focus, demonstrates that the cornea is marked by a prodigious number of minute decussating lines, giving a kind of granular appearance to the whole convexity: but when microscopically examined, it exhibits a continued surface of convex hexagons, and if cut from the head, and cleared from its internal pigment, it appears perfectly transparent, and seems to consist of an infinity of hexagonal lenses of equal convexity on both surfaces. This is a subject on which much might be said; but the compass of the present publication forbids too circumstantial a description of minute and disputable particulars. It may be sufficient to observe that on each eye of this animal, according to the computation of Lewenhoeck, there are about 12,544 of these lenses."

To those who would study in detail the members of this group, we would recommend the volume of Rambur in the "Suites à Buffon," and the works of Van der Linden, De Selys Longchamps, and especially Charpentier. In this country, J. C. Dale, Esq. F.L.S., has made the group a special subject of study, and Mr. W. Evans has published rough figures of all the British species, which

may prove useful in identifying them. Dragon-flies are often found in a fossil state, as early as in the lias formation. [See PETALURA.]

DRILL. [See ARE.]

DRIVER ANT. The local name given to a species of Hymenopterous insect belonging to the family of Ants. Its name is *Anomma arcens*. The following very interesting account is derived from a paper by the Rev. Dr. Savage, an American missionary on the coast of West Africa, and published in the "Transactions of the Entomological Society" for 1847.

The writer prefaces his narrative by saying that he is not aware that the insect in question has ever been described, or that it exists in any of the European cabinets; but he thinks it is, without doubt, that of which Mr. Smeathman speaks, when he says, "one species, which seems at times to have no fixed habitation, ranges about in vast armies. By being furnished with very strong jaws, they can attack any animal whatever that impedes their progress, and there is no escape but by immediate flight or instant retreat to the water. The inhabitants of the negro villages are frequently obliged to abandon their dwellings, taking with them their children, &c., and wait till the ants have passed." Dr. Savage says it is evidently closely allied to the *Atta cephalotes* of Fabricius, found in the West Indies and South America, and like that named by the French "*Fourni de visite*," would be not inappropriately styled the "visiting ant," though he considers the appellation *Driver* more significant of its habits. "Its domicile," he says, "if such it may be called, consists of a shallow excavation under the roots of trees, shelving rocks, and almost any other substance that will afford a shelter; not originating with themselves, but adopted and completed as the wants of their community may require; their mode of life not admitting of cells and magazines, and other interior arrangements, by which the domiciles of other ants more retiring and less aggressive in their habits are characterized.

"Their sallies are made in cloudy days, and in the night, chiefly in the latter. This is owing to the un congenial influence of the sun, an exposure to the direct rays of which, especially when the power is increased by reflection, is almost immediately fatal. If they should be detained abroad till late in the morning of a sunny day by the quantity of their prey, they will construct arches over their path, of dirt agglutinated by a fluid excreted from their mouth. If their way should run under thick grass, sticks, &c., affording sufficient shelter, the arch is dispensed with; if not, so much dirt is added as is necessary to cke out the arch in connection with them. In the rainy season, or in a succession of cloudy days, this arch is seldom visible; their path, however, is very distinct, presenting a beaten appearance, and freedom from every thing movable. They are evidently economists in time and labour: for if a crevice, fissure in the ground, passage under stones, &c., come in their

way, they will adopt them as a substitute for the arch. This covered way seems to be designed in part for the protection of workers in transporting prey, pupæ, &c., but chiefly against the direct rays of the sun, an exposure to which, in places where the REFLECTION is strong, is certain death in less than two minutes. When the sun's rays are intercepted for days, the arch is wanting; and, even with the arch, in a bright strong sunshine, masses of the Drivers are found under the thick grass in holes and other places, regaling themselves in the shade till the decline of the sun, when their work is renewed with their characteristic vigour.

"In cloudy days, when on their predatory excursions, or migrating, an arch for the protection of the workers, &c. is constructed of the bodies of their largest class. Their widely extended jaws, long slender limbs, and projecting antennæ intertwining, form a sort of net-work that seems to answer well their object. Whenever an alarm is given, the arch is instantly broken, and the ants, joining others of the same class on the outside of the line, who seem to be acting as commanders, guides, and scouts, run about in a furious manner in pursuit of the enemy. If the alarm should prove to be without foundation, the victory won, or danger passed, the arch is quickly removed, and the main column marches forward as before in all the order of an intellectual military discipline.

"I will here describe an attempt that I recently made to destroy one of their communities, which, with the facts in the order in which they transpired, and the collateral circumstances attending it, will fairly illustrate many of their habits. My observations were made in part at my former station (Cape Palmas), where I resided nearly eight years. I have been at my present station about eight months. During the first four months of the latter period I was greatly annoyed by the frequent visitations and ravages of these insects; at one time literally driving out every member of the female department of the school; at another the male department; then the inmates of my own dwelling; again, attacking my horse, then my pigs, fowls, &c. &c.; nothing, in fine, possessing animal life escaping their assaults. They always pounced upon us at night, and generally when our senses were reposeing in sleep. Occasionally we were apprised of their designs at nightfall by a few suspicious individuals lurking in the vicinity in advance of the main body, but mostly they took us by surprise. At last their annoyance seemed to have reached the highest point of our forbearance, and a resolution was forthwith taken to discover their habitation, and, if possible, expel them from the vicinity. Accordingly I commenced cutting over the premises, and had proceeded as far as two-thirds the way down the mound on which my dwellings stand, when, beneath a shelving rock of decomposing granite, their haunt was discovered. They had been roused by the noise and efforts of the workmen, and had come forth in incalculable numbers for defence, literally blackening the surrounding grass and shrubbery. Lines of ants, going and com-

ing agreeably to the rules of their order, were running in opposite directions. Their paths were very distinct and well trodden, of about an inch in width. In other directions were seen covered ways forsaken, the object of their formation no longer existing,—no prey having been discovered, or, if found, being disposed of,—and other regions lying open for exploration. Their numbers could not be computed; millions on millions seemed to be there, besides thousands that were going and coming with astonishing speed and alacrity.

"In attempting their destruction I adopted the mode of the natives, which is, to ignite on the spot a collection of the dried leaves of a species of *Corypha* (fan palm of this coast), about six feet in diameter, and dried grass, with other combustible matter. A fire of great intensity was thus kindled, which continued to burn for a considerable time. This I supposed would be the last of our troublesome neighbours. Two days after, however, on going to the spot for the purpose of examining into their domicile, I was surprised to see a tree at a short distance, about eighteen inches in diameter, to the height of four feet from the ground, with the adjacent plants and earth, perfectly black with them. From the lower limbs (four feet high) were festoons or lines of the size of a man's thumb, reaching to the plants and ground below, consisting entirely of these insects; others were ascending and descending upon them, thus holding free and ready communication with the lower and upper portion of this dense mass. One of these festoons I saw in the act of formation; it was a good way advanced when first observed: ant after ant coming down from above, extending their long limbs and opening wide their jaws, gradually lengthened out the living chain till it touched the broad leaf of a *Canna coccinea* below. It now swung to and fro in the wind, the terminal ant the meanwhile endeavouring to attach it by his jaws and legs to the leaf; not succeeding, another ant of the same class (the very largest) was seen to ascend the plant, and, fixing his hind legs with the apex of the abdomen firmly to the leaf under the vibrating column, then reaching forth his fore legs and opening wide his jaws, closed in with his companion from above, and thus completed the most curious ladder in the world."

In about two hours Dr. Savage visited the spot again, when the hanging lines or festoons were gone, and about half of the mass also; some below the surface, others on their predatory excursions; and they again underwent the fiery ordeal, which urged them forwards, and they marched on with all their former celerity. Next morning he found them still engaged in removing. Thousands and tens of thousands must have been destroyed by the two fires, and yet apparently their numbers were undiminished. Neither on this nor any other occasion did he detect a winged individual, though it was the season when such are to be found in all communities of ants not apterous.

"Their mode of biting differs from that of the soldiers among the *Termes*. The mandibles of the latter are flat and sharp, and move in a cross direction, cutting in the manner of scissors. The mandibles of the Driver of the first class are very prominent and formidable, strongly hooked, having one tooth; those of the second class are flatter, sharper, and armed with two strong teeth, the edges finely serrated, and admirably calculated for lacerating and cutting muscular fibre. The onset of the former is with a grasp that causes their victim to start and wince as if life were in danger; their mandibles are fixed so strongly into the flesh, and their hold retained with such pertinacity, that a separation is effected often only by a dismemberment of the body. If permitted to retain their hold, the motion of their jaws is alternately from one side to the other, penetrating deeper and deeper at every stroke. With the second class there is not only this gradual penetration, but at the same time lacerating and cutting of the flesh, with an approximation of the jaws at each effort. This difference in the form and motion in the two classes led me to infer a difference of duties or office in their economy. This impression has been confirmed by repeated observations. To the first class, it would appear, is assigned the defence of the community; it is theirs also to attack and disable their prey. The second lacerate and cut the flesh, and are assisted by the first in tearing it off. Upon the third, who appear to be especially the labourers, devolves the burthen of transportation, whether of prey or pupæ. They are seen to be assisted often by the second class, and, when the prey is too large for either, the first is called in.

They carry their pupæ and prey longitudinally under their bodies, held firmly between their mandibles and legs, the latter of which are admirably calculated by their length and slenderness for this purpose; and the freedom and ease with which they carry their burthen is truly surprising.—Whenever a stream of water intercepts their course in their excursions and migrations, if it should not be extensive they compass it, but if otherwise, they make a line or chain of one another, gradually extending themselves by numbers across, till a connection is formed with the opposite side, and thus a bridge is constructed, over which the main body passes in safety.—Their tenacity of life appears to be truly extraordinary. This was evinced by a series of experiments. An individual of the largest class was submerged to the bottom of a glass of water, where it struggled for about three quarters of an hour, and then apparently expired; but it revived in about ten minutes after it was taken out, exhibiting about as much vitality and ferocity as before. It was re-submerged for five hours, with like results. It was submerged the third time, and kept under water for twelve hours. When taken out it revived, and continued to exhibit signs of life for about twelve hours more, and then expired. Various other experiments were tried. The head of one of the largest class,

when dis severed from the body, grasped the finger of an attendant so furiously as to cause an immediate flow of blood; another decapitated head retained its power of biting so as to draw blood, precisely in the manner of the insect in possession of all its parts and powers, twenty-four hours after decapitation; while the body to which it belonged lived more than forty-eight hours!

"I know of no insect," says Dr. Savage, "more ferocious and determined upon victory. They fiercely attack anything that comes in their way,—'conquer or die' is their motto. Yet they are not without their uses in the economy of nature. They keep down the more rapid increase of noxious insects and smaller reptiles; consume much dead animal matter, which is constantly occurring, decaying, becoming offensive, and thus vitiating the atmosphere, and, which is by no means the least important in the Torrid Zone, often compelling the inhabitants to keep their dwellings, towns, and their vicinity, in a state of comparative cleanliness. The dread of them is upon every living thing. It may be literally said that they are against everything, and everything against them. I have known my dog, on meeting them in the road, instead of running any risk by leaping over them, go a great distance round to avoid their well-known bite. My donkey has more than once stopped so suddenly and turned, as to throw me over her head, or to one side, and when urged forward, leaped far over the line.—They will soon kill the largest animal if confined. They attack lizards, guanas, snakes, &c., with complete success. We have lost several animals by them, monkeys, pigs, fowls, &c. The severity of their bite, increased to great intensity by vast numbers, it is impossible to conceive. We may easily believe that it would prove fatal to almost any animal in confinement. They have been known to destroy the *Python natalensis*, our largest serpent. When gorged with prey it lies powerless for days; then, monster as it is, it easily becomes their victim.—Their entrance into a house is soon known by the simultaneous and universal movement of rats, mice, lizards, *Blapsula*, *Blattida*, and of the numerous vermin that infest our dwellings.—They are decidedly carnivorous in their propensities. Fresh meat of all kinds is their favourite food; fresh oils they also love, especially that of the *Elais guineensis*, either in the fruit or expressed. It is not true, however, that they devour every thing eatable by us in our houses; there are many articles which form an exception. If a heap of rubbish comes within their route, they invariably explore it, when larvæ and insects of all orders may be seen borne off in triumph,—especially the former."

DROMEDARY. [See CAMEL.]

DROMIA. A genus of Crustacea, somewhat allied to *Dorippe*, of which there are several species. The one figured (*Dromia vulgaris*) is very common in the Mediterranean; its carapace is almost globular; the two posterior pairs of legs are raised above

"the plane" of the others; hence the division containing it is named *NOTOPODA*. They are each furnished with two sharp

SPONGE CRAB.—(*DROMIA VULGARIS*.)

curved claws, which enable the crab to hold fast by pieces of sponges, medusæ, or other marine productions, under which it conceals itself. In the British Museum collection are some very interesting specimens of a common West Indian species (*Dromia lator*) with pieces of sponge so attached, into which the convexity of the back of the carapace is very nicely fitted.

DRONE. The male honey-bee. [See *BEE*.]

DRUMMER. [See *BLATTA*.]

DRYOPITHECIUS. [See *SUPPLEMENT*.]

DUCK. (*Anas*.) A very extensive and natural genus of water-birds, found in all parts of the world. They feed in great part upon animal matter, such as insects and molluscs; as well as upon vegetables and grain: they are generally seen upon the lakes and rivers of the interior, though they occasionally resort to the sea-shore. Ducks can all swim and dive with facility; they can all fly well; and they can all walk, though frequently with difficulty. They feed on soft substances, such as fresh-water insects and tender aquatic plants, which they procure near the surface, or at the bottom in shallow muddy places, and worms and slugs, which they search for among the grass. Their distinguishing characters are these: the beak is shorter in proportion than that of the goose, strong, flat, or depressed, and commonly furnished with a nail at the extremity. The feet are proportionably larger than those of the goose kind, the middle toe being the longest; the legs are shorter, and placed farther backwards; the back is flatter; and the body is more compressed. The nostrils are small and oval; and the tongue is broad, the edges near the base being fringed. There are numerous species of this genus, some inhabiting the fresh water, and others the sea.

The **COMMON WILD DUCK**, or **MALLARD** (*Anas boschas*), is the original stock of the tame or domesticated Duck, and appears to have been reclaimed at a very early period. This bird measures about twenty-three inches in length, thirty-five in breadth, and is two pounds and a half in weight. The bill is of a yellowish green colour, and the head and neck are a deep shining green: a

circle of white surrounds the neck, to about three-fourths of its circumference: the upper part of the breast and shoulders is of a deep vinous chestnut; the breast and belly are gray, marked with transverse speckled lines of a dusky hue; and the scapulars are white, elegantly barred with brown. The spot on the wing is a rich purple; and the tail is composed of twenty-four feathers. The male of this species is distinguished by four middle feathers, which are black, and strongly curled upwards; but of these the female is destitute. Indeed the plumage of the female partakes of none of the male's beauties, except the spot on the wings. She makes her nest, lays from ten to sixteen greenish-white eggs, and rears her young generally in the most sequestered mosses or bogs, far from the haunts of man, and hidden from his sight among high grass, reeds, and bushes. Like the rest of the Duck tribe, the Mallards, in prodigious numbers, quit the north at the end of autumn, and, migrating southward, arrive at the beginning of winter in large flocks, and spread themselves over all the loughs and marshy wastes in the British isles. They pair in the spring, when the greater part of them again retire northward to breed; but many straggling pairs stay with us: they, as well as preceding colonists of their tribes, remain to rear their young, who become natives, and remain with us throughout the year.

WILD DUCK.—(*ANAS BOSCHAS*.)

The flesh of the Wild Duck is held in general estimation, and various methods are resorted to, in order to obtain these birds in quantities. To describe even a tithe part of these various contrivances is not our purpose; but it is necessary to state that the decoy is by far the most favourite method, and is likely long to continue so, as by that species of stratagem Wild Ducks are taken by thousands at a time; whereas all the other schemes of lying in ambush, shooting, baited hooks, wading in the water with the head covered, &c., are attended with much watching, toil, and fatigue, and are also comparatively trifling in point of success. They abound in Lincolnshire, and are there taken in great numbers. These decoys are usually thus prepared and conducted:—It is generally made where there is a large pond surrounded with wood, and beyond that a marshy and uncultivated country. On the south and north sides of the pond, two or three ditches or channels should be made, broader towards the water, and gradually narrowing till they terminate in a point: these channels should be covered

over with nets, supported by hooped sticks, so as to form a vault or arch growing narrower and narrower to the point, where it should be terminated by a tunnel net: along the banks of these netted channels many hedges should be made of reeds slanting to the edges of the gutters, their acute angles being toward the side next the pool; and the whole apparatus should also be concealed from the pool by a marginal hedge of reeds, behind which the operations of the fowler are conducted. Provided with a number of Ducks termed decoys, which are rendered tame by education, and accustomed to attend their master on being summoned by a whistle, the fowler sets them to feed at the mouths of the pipes. No sooner does the evening commence, than the decoy rises, to use the language of fowlers, and the wild fowl feed during the night. Should the evening be still, the noise of their wings during their flight is heard at a considerable distance, and produces no unpleasant sensation. The fowler, whenever a fit opportunity offers, and he sees his decoy covered with fowl, walks about the pond, and observes into what pipe or channel the assembled ducks may be enticed or driven with the greatest facility: then, throwing hemp-seed, or some similar allurement which will float on the surface, at the entrance of the pipe, and along its extent, he whistles to his decoy-ducks, which instantly obeying the summons, approach, in expectation of being fed as usual; whither also they are followed by a whole flock of the wild ones, unsuspecting of their meditated ruin. However, their sense of smelling being extremely acute, they would speedily discover the ambuscade, did not the fowler hold a piece of burning turf to his nose, against which he constantly breathes, and thereby prevents the effluvia of his person from affecting their very exquisite senses. The Wild Ducks, therefore, in following the decoy ones, are conducted by them into the broad mouth of the pipe, without the smallest suspicion of danger, the fowler being still hid behind one of the hedges: nevertheless, when they have proceeded a short way up the pipe, and perceive it to grow narrower, they begin to apprehend danger and endeavour to return; but in this attempt they are prevented by the fowler, who now makes his appearance at the broad end below. Thus surprised, intimidated, and utterly unable to rise because of the surrounding net, the only remaining way of escape seems to be through the narrow-funnelled net at the bottom; into which they fly, and are instantly taken.

Pennant had an account sent him of the produce of ten decoys, which, in one winter, amounted to thirty-two thousand two hundred. In Picardy in France, also, vast numbers are taken in decoys, and sold in the Paris market, where, in one season, 30,000 francs have been paid for the produce of the small lake of St. Lambert. Wilson, the celebrated American ornithologist, enumerates several simple and effective contrivances made use of in America for the capture of these wary birds. In some ponds

frequented by them, five or six wooden figures, cut and painted to represent ducks, and sunk by pieces of lead nailed to the bottom, so as to float at the usual depth on the surface, are anchored in a favourable position to be raked from a concealment of brush, &c. These attract the passing flock, which alight, and thus expose themselves to certain destruction. In winter, when detached pieces of ice are occasionally floating in the river, some of the sportsmen on the Delaware paint their boats white, and laying themselves flat in the bottom, direct them almost imperceptibly near a flock, before the ducks have distinguished them from a floating piece of ice. On land, another stratagem is sometimes practised with great success. A tight hoghead is sunk in the marsh, or mud, near the place where ducks are accustomed to feed at low water, and where, otherwise, there is no shelter; the edges and top are carefully concealed with tufts of long coarse grass, and reeds or sedg. From within this the sportsman watches his collected prey, and usually commits great havoc. In China, the sportsman covers his head with a calabash, pierced with eyeholes, and, thus equipped, wades into the water, keeping only his head above the surface, and, on arriving amidst a flock, seizes them by the legs, fastens them to his girdle, and takes as many as he wishes, without disturbing the rest.

The TAME DUCK. Some individuals in a domestic state appear in nearly the same plumage as the wild ones; others vary greatly from them, as well as from each other, and are marked with nearly every colour; but all the males or drakes still retain the curled feathers of the tail. The Tame Duck is, however, of a more dull and less elegant form and appearance than the Wild, domestication having deprived it of its lofty gait, long tapering neck, and sprightly eyes. Tame Ducks are reared with more facility than perhaps most other domestic animals. The very instincts of the young direct them to their favourite element; and though they are sometimes hatched and conducted by hens, they seem to contern the admonitions of their leaders; a circumstance which seems to indicate that all birds receive their manners rather from nature than education, and attain their various perfections without the help of any other guide.

There appears to be good reason for placing duck-eggs under a hen. The Duck generally proves a heedless, inattentive mother; for she frequently leaves her eggs till they become corrupted, and even seems to forget that she is entrusted with the charge: she is also equally regardless of her young brood when they are produced; for she only leads them forth to the water, and then seems to think she has made sufficient provision for them. The hen, on the contrary, who is an indefatigable nurse, broods with unwearied assiduity, and generally hatches a duckling from every egg with which she is entrusted: she does not, indeed, conduct her young to the water, because that is contrary to her nature; but she always keeps a watchful

eye over them when they approach the brink. Should the rat, the weasel, or other natural enemy of the feathered tribe, attempt to seize any of them, the hen instantly affords them her best protection; and, leading her supposititious brood to the house when fired with paddling, there nourishes them with all the instinctive ardour of maternal regard. "The village school-boy," as Bewick says, "witnesses with delight the nntie movements of the shapeless little brood, sometimes under the charge of a foster-mother, who, with anxious fears, paddles by the brink, and utters her unavailing cries, while the Ducklings, regardless of her warnings, and rejoicing in the clement so well adapted to their nature, are splashing over each other beneath the peudent foliage; or, in eager pursuit, snap at their insect prey on the surface, or plunge after them to the bottom; some, meanwhile, are seen perpendicularly suspended, with the tail only above water, engaged in the general search after food."

There are many different varieties of the Tame Duck; the most obvious distinction, however, between the wild and tame species lies in the colour of their feet; those of the tame being black, and the wild yellow. As we before observed, the common species of Tame Ducks derive their origin from the Mallard, and may be traced to that fowl by unerring characters. Tame Ducks are an extremely advantageous kind of poultry; as they subsist on scattered corn, the refuse of vegetable and animal substances, worms, snails, and insects. They lay a great number of eggs annually; require very little attendance when sitting; and, with respect to Ducklings, they may be easily fattened in the course of three or four weeks with any kind of pulse or grain and water.

MUSCOVY DUCK, or MUSK DUCK. (*Cafrina moschata*.) This bird, which takes its name from its musky smell, and not from its being originally obtained from Russia, as is supposed, is upwards of two feet in length. In its wild state it is entirely of a black colour, with glosses of blue and green, and white wing-coverts; but when domesticated it varies very considerably: its usual appearance, however, may be thus described. The crown of the head is slightly tufted, and black; the cheeks and fore part of the neck white, irregularly marked with black; the belly chiefly white, and the general colour of the rest of the plumage deep brown, darkest and glossed with green on the back, rump, quills, and tail, the two outer feathers of the latter, and the three first primaries being white: the legs and feet are short, thick, and red. They are more prolific and sit shorter than other ducks; and their eggs, which are frequently tinged with green, are larger and rounder than those of other species.

CANVAS-BACKED DUCK, or PO-CHARD. (*Aythya vallisneria*.) The zoologist is indebted to the indefatigable Wilson for the first account of this much esteemed species. The Canvas-back is two feet long, and three feet wide, and when in good order

weighs three pounds. The beak is large, and of a glossy black; the head and part of the neck of a rich glossy reddish-chestnut hue, ending in a broad space of black that covers the upper part of the breast: back, scapulars,

CANVAS-BACKED DUCK.
(*AYTHYA VALLISNERIA*.)

lower part of the breast, and belly, white, faintly marked with an infinite number of transverse wavy lines, or points: wing-coverts gray spotted: tail very short, and pointed; legs and feet very pale ash. The female is smaller, and not so brightly coloured as the male. These birds arrive in the United States, from the north, about the middle of October, and, principally, assemble in the numerous rivers in the neighbourhood of the Chesapeake bay. When they first arrive they are very lean; but from the abundance of their favourite food, they become fat about November. From the great demand for these ducks, and the high price they fetch, various methods are employed to decoy them.

Besides the species we have described, there are many, for which we can only find room for very brief notices. The **SCAUT DUCK** (*Fuligula marila*), somewhat smaller than the common duck. In North America, a variety of this species is better known by the name of the Blue-bill, and is common both to the fresh-water rivers and sea-shores in

SCAUP DUCK.—(*FULIGULA MARILA*: VAR.)

winter, those which frequent the latter being generally much the fattest, on account of the greater abundance of food along the coast. The **GOLDEN-EYE** (*Clangula glaucion*), the bill of which is black, short, and broad at the base; the head is large, and of a deep black hue, glossed with green; and at each angle of the mouth there is a large white spot. The **BLACK DUCK**, or **SCOTER** (*Oidemia nigra*); a bird whose flavour is so rank and fishy, as to be exempted, with a few others, from the interdict which forbids Roman Catholics the use of animal food on certain days, on the supposition of their being

cold-blooded, and partaking of the nature of fish. The **PIED DUCK** (*Anas Labradoria*); a beautiful and rare species, peculiar to America. **CHINESE DUCK** (*Anas galericulata*); a remarkable bird somewhat less than a widgeon. The **SCUMMER or WOOD DUCK** (*Aix sponsa*); not more remarkable for its

SUMMER DUCK.—(*AIX SPONSA*.)

great beauty, in which it stands pre-eminent, than for its habits, its migrations being directly opposed to those of the other species. **AUTUMNAL DUCK** (*Anas autumnalis*); native of the West India islands and South America, where the inhabitants frequently keep them in the farm-yards. **TREE DUCK**, or **WHISTLING DUCK**, (*Anas arborea*); this also is an inhabitant of the West India islands and the adjacent continent of America. We learn from Mr. Gosse's "Birds of Jamaica," that its singular whistling note is peculiarly shrill, and is uttered in its crepuscular flights to and from its feeding places, and also when it is alarmed. He also says these birds are much dreaded by those who plant Guinea-corn; and that "numerous flocks of both young and old birds frequent the millet-fields from December till the end of February, when this corn is reaped." They are most busy in their depredations on moonlight nights; and as they sweep round in circles, their remarkable whistle always betrays their movements." Another remarkable peculiarity is thus recorded: "The Whistling Duck endeavours to save her young, when pursued, by throwing herself into the man's way; that is, by rushing up so close to him as to draw his attention, that her young, who are very active, may have an opportunity of escaping. Accordingly, the man, seeing the duck so near him, looking upon her as a much better prize than the young ones, leaves pursuing the ducklings, and endeavours to catch the subtil dame, who runs before, but takes special care to keep out of his reach; yet stopping in front of him occasionally, to make him renew the pursuit, till the young are entirely out of danger; when she flies away, leaving her pursuer to fret at his double disappointment." **LONG-TAILED DUCK** (*Harelda glacialis*); remarkable for the long and slender feathers of its tail. This Duck is very generally known along the shores of the Chesapeake Bay by the name of the *South-southerly*, from the singularity of its cry, something imitative of the sound of those words; and also, that, when very clamorous, they are supposed to betoken a southerly wind. They inhabit the bays and coasts of North America

during the winter only; are rarely found in the marshes, but keep in the channel, diving for small shell-fish, which are their principal food. In passing to and from the bays, sometimes in vast flocks, particularly towards evening, their loud and confused noise may be heard in calm weather at the distance of several miles. They fly very swiftly, take short excursions, and are lively restless birds. Their native regions are in the north, where great numbers of them remain during the whole year; part only of the vast family migrating south to avoid the severest rigours of that climate. They are common to the whole northern hemisphere. In the Orkneys they are met with in considerable flocks from October to April; frequent in Sweden, Lapland, and Russia; and are said to breed at Hudson's Bay, making their nest among the grass near the sea, like the eider duck, and about the middle of June lay from ten to fourteen bluish-white

LONG-TAILED DUCK.—(*HARELDA GLACIALIS*.)

eggs, the size of those of a pullet. When the young are hatched, the mother carries them to the water in her bill. The nest is lined with the down of her breast, which is accounted equally valuable with that of the eider duck, were it to be had in the same quantity. They come to England only in very severe winters, and then but in small straggling parties. **TUFTED DUCK** (*Anas cristata*), found in the arctic regions of both continents, and migrating to southern countries in the winter: on the top of the head is a crest consisting of long and slender feathers, which, with the head, neck, and breast, are black, glossed with violet and green. **PINTAIL DUCK** (*Dafila acuta*); remarkable for the pointed form of its tail; it is abundant in both hemispheres. The **NILOTIC MUSK DUCK** (*Anas Nilotica*); between the size of the Pintail Duck and the Goose, but stands higher on its legs. It inhabits the Nile, in Upper Egypt; is easily tamed, and lives among other domestic poultry. **GREY-HEADED DUCK** (*Somateria spectabilis*); with red bill, legs, and feet: native of Hudson's Bay. The **GREAT BLACK DUCK** (*Oidemia perspicillata*); a species considerably larger than the common Duck. **STELLATED DUCK**; a species distinguished by its eyes, which are placed higher than usual in an oval black spot; but its principal characteristic is a large white star on its back. The **MADEGASCAR DUCK**; a large and brilliantly-coloured species: the bill of a yellowish-brown colour; the head and neck of a dusky green; and the back is of a deep purple.

the long feathers of the wings are adorned with red eyes; and the legs and feet are of an orange hue. The **HOOK-BILLED DUCK** (*Anas adunca*), which differs but little from the common Wild Duck except in the bill. The **FRECKLED DUCK** (*Anas nasosa*); a very rare species which inhabits the neighbourhood of Swan River, in Australia, but from its scarcity it is little known either to the colonists or the natives. According to Mr. Gould's description of the specimen in his possession, the whole of the plumage is dark brown, minutely freckled and spotted with irregular oblong marks of white in the direction of the feathers; the under surface the same, but lighter and tinged with buff; wings without a speculum; primaries plain brown; irides light brown; bill greenish gray, becoming much darker at the tip; legs bluish green.

DUGONG. (*Halicore*.) A marine animal, herbivorous in regard to its food, and fish-like in its form. It ranks among the *Cetocæ*; is about seven or eight feet in length; and

DUGONG.—(HALICORE DUGONG)

has two large permanent incisive teeth in the upper jaw, and four molar teeth above and below. It is a native of the Indian seas, being common among the islands of the Indian Archipelago, and visiting also the coasts of New Holland. Its flesh is said to be tender, and not unlike beef. Professor Owen, in the Appendix to Juke's Voyage of H. M. S. Fly, has described a new species from the Eastern seas.

DUNLIN. (*Pelidna*.) A genus of birds belonging to the *Scolopocidæ* or Snipe tribe. The Dunlins in appearance resemble larks; they fly in troops near the coast; and lay their eggs in the sand. There are several species; but it will be sufficient to describe one of them:—**RED DUNLIN.** (*Pelidna subarctica*.) This bird is about eight inches in length; top of the head is black, edged with rufous; the forehead and throat are white dotted with brown; the nape is red, with small longitudinal black dashes; the neck, breast, and under parts are red chestnut, sometimes marked with black spot or variegated with white; tail coverts white, transversely rayed with black and red; the back, scapulars, and large wing-coverts of a deep black; on the edge of the feathers is a range of angulated bright red spots, the greater portion of which are terminated with bright ash; the tail is of a dusky ash, bordered with white. The beak is black; and the legs are brown. This bird is a native of most parts of Europe, and is

sometimes seen on the British coasts. It rarely appears at any considerable distance inland; but migrates in the spring and autumn. It lays four or five eggs, of a dirty white colour, spotted with brown; and its flesh is esteemed a delicacy. The names of the other species are the **PIERRE DUNLIN**, (*Pelidna variabilis*); **LITTLE DUNLIN** (*Pelidna pusilla*); **TEMMINCK'S DUNLIN** (*Pelidna Temminckii*); **MINUTE DUNLIN** (*Pelidna minuta*); and the **St. DOMINGO DUNLIN**, (*Pelidna Dominicensis*).

DYNASTIDÆ. A family of Lamellicorn Coleoptera, comprising several beetles remarkable for their size, strength, and formidable appearance. The males are pre-eminently distinguished by various singular protuberances, horns, or tubercles, arising from the head or thorax, and often from both of these parts of the body. "It must be borne in mind, however," as Mr. Westwood observes, "that these horns are immovable portions of the horny skeleton, and offer no real analogy with the horns of the mammalia; although it is interesting, in respect to the analogies existing in remote tribes of the animal kingdom, that the quadrupeds which are cornuted are herbivorous, and as comparatively harmless as the Dynastidæ." They chiefly inhabit the tropical regions, excavating burrows in the earth,

HERCULES BEETLE.—(DYNASTES HERCULES.)

where they conceal themselves during the day, or reside in the decomposed trunks of trees; and they are generally of a dark rich brown or chestnut colour. On the approach of night they leave their retreats, and run about the footpaths in woods, or fly around the trees to a considerable height, with a

loud humming noise. It is believed that they subsist principally upon putrescent wood and the detritus of other vegetable matter. Among the most remarkable may be mentioned the *Dynastes Hercules*, or **HERCULES BEETLE**. It is usually about four, but sometimes measures not less than five, or even six inches in length; the elytra are of a smooth surface, of a bluish or brownish-gray colour, and generally marked with several small round deep-black spots, of different sizes: the head and limbs are jet black; from the upper part of the thorax proceeds a horn or process of enormous length in proportion to the body, sharp at the tip, curving slightly downwards, and furnished throughout its whole length with a fine, short, velvet-like pile, of a brownish orange colour: from the front of the head proceeds also a strong horn, about two-thirds the length of the former, toothed on its upper surface, but not covered with any of the velvet-like pile. This species is a native of several parts of South America, where great numbers are sometimes seen on the tree called the *Mammia Americana*, and have been said by some travellers to rasp off the rind of the slender branches by working nimbly round them with the horns, till they cause the juice to flow, which they drink to intoxication, and thus fall senseless from the tree. This, however, has a very fabulous air, nor, although the account has been often repeated, do we find it any where sufficiently well authenticated to depend upon; in short, the structure of the horns would render it impossible. The female is destitute both of the frontal and thoracic horn, and but for her large size would hardly be regarded as her lord's mate.

The next species, *Megasoma elephas*, or **ELEPHANT BEETLE**, is also a native of South

at least three inches long. Our figure will show better than any description its form and general appearance. It is covered with a yellowish gray down, which is very short and thickly set: the head is furnished with a long arched horn, which is bifid at the extremity, of a blackish colour, with a large tubercle at the base, directed forwards: the thorax has two small smooth tubercles in the middle, and a strong somewhat oblique horn on each side: the front legs are considerably arched. The next species figured is from the Eastern Islands. It is the *Chalcosoma Atlas*, or **Atlas Beetle**. It is of a highly polished metallic surface:

ATLAS BEETLE.—(*CHALCOSOMA ATLAS*.)

the horns on the head and thorax vary very much in the different specimens; but our figure is taken from a specimen in which these prominences are well developed. It seems to be far from uncommon in the Philippine Islands. There are fine specimens of it and many other species of *Dynastidae* in the collection of the British Museum. We may here say that the females of the *Dynastidae* are devoid of spines or projections on the head and thorax, just like our British *Onthophagi*, and that, like them, the males have the head more or less armed, according to the quality and quantity of the food they have taken in the larva state. This observation, as far as regards European Lamellicorn beetles, is made by M. Mulsant of Lyons, in his excellent and extensive work on the Coleoptera of France.

DYTISCUS: DYTISCIDÆ. A genus and family of insects belonging to the aquatic carnivora; which during their larva and perfect states live in water, but quit that element to undergo their metamorphoses, and to pass the time of their pupa condition. The *Dytiscus marginalis* (one of the largest European species) is common in stagnant waters; it is an inch or rather more in length, and is of a dark olive colour, with the

ELEPHANT BEETLE.—(*MEGASOMA ELEPHAS*.)

America (having been brought from Venezuela by Mr. David Dyson), though for a long time it was erroneously supposed to be a native of Africa. Some specimens are

thorax and wing-sheaths bordered with yellow. The larva of this insect in shape much more resembles the shrimp tribe than that of its parent. It measures, when full grown, about two inches and a half in length, and is of a pale yellowish-brown colour, with a high degree of transparency: the head is very large, rather flat, and is furnished with a pair of very strong curved forceps, with which it attacks its prey: its legs are slender, and its abdomen is very considerably lengthened, and ciliated on each side the tail, which terminates in a divided fin or process. The larva is very bold and voracious, committing great ravages not only among winter insects, but even among small fishes, and is therefore considered one of the most mischievous animals that can infest a fish-pond. When full-grown, the larva betakes itself to the adjoining banks, where it changes into a chrysalis of a whitish colour. There are numerous species of this genus, but none so large or destructive as the one here described: some of them are, by comparison, extremely minute.

A WATER-BEEZLE
(HYDATICUS INTERMIXTUS.)

As an illustration of this family, we have figured (after Sturm) the *Hydaticus intermixtus*, belonging to a genus of *Dytiscidae*, of which some species are found in this country. Dr. Schaum has given in "the Zoologist" a revision of all the British species of this family. In the work of Dr. Aubé of Paris, descriptions of the numerous species and genera of Water Beetles will be found, while in the pages of the "List of Hydrocanthari in the British Museum Collection" will be seen how very extensive and how universally distributed is the family of Water Beetles.

DZERON, or CHINESE ANTELOPE. (*Antelope gutturosa*.) This species of Antelope inhabits China, Thibet, and Tartary, chiefly frequenting the dry and rocky plains, and feeding on the scanty herbage which those barren localities supply. The length of this animal is about four feet and a half: the horns, nine inches long, of an opaque yellow colour, and having a backward direction, are annulated nearly to the tips, and diverge considerably upwards, though the points bend towards each other. The head is rather clumsy; the nose obtuse; the ears small and pointed; and on the middle of the neck grows a large protuberance, occasioned by the peculiar structure of the windpipe. It is of a tawny hue on the upper parts, and

white beneath; but in winter the hair grows long, thick, and hoary. This species, which the Chinese call *Whang Yang*, or Yellow Goat, is extremely swift and active, but naturally shy and timid. During the winter season they herd in great numbers, but separate again on the approach of spring. The Tartars hunt them with the utmost eagerness, and esteem their flesh very delicious food: the horns form a considerable article of commerce, and are in great request among the Chinese: the female has no horns. Specimens of this Antelope are in the British Museum collection. It has never, however, been brought alive to this country.

EAGLE. (*Aquila*.) Pre-eminent for courage, strength, and boldness among predaceous birds, is the daring and majestic Eagle. This time-honoured monarch of the feathered tribes, which in the mythology of Greece and Rome was deemed worthy to rank as the chosen associate of Jupiter, was ever regarded as an emblem of dignity and might, and still has the reputation of being equally magnanimous, fierce, and voracious. What the Lion is among quadrupeds, that the Eagle is presumed to be among birds; one who disdains all petty plunder, and pursues only such prey as would seem to be worthy of conquest. This laudatory character of the king of birds, however, though true in the main, and generally acquiesced in, is, it must be confessed, more poetically descriptive than logically accurate; but while, in our zoological character, we are bound to make this admission, far be it from us to disparage the "bird of Jove," or to pluck a single plume from his upsoaring wing. Eagles are distinguished by the feathering of the *tarsi* down to the very base of the claws; and the males are smaller than the females; their plumage varying considerably, according to age and other circumstances. Of all the feathered tribe the Eagle soars the highest; and of all others also it has the strongest and most piercing sight. Though extremely powerful when on the wing, the joints of its legs being rather stiff, it finds some difficulty in rising again after a descent; yet, if not instantly pursued, it will easily carry off a goose or other bird equally large. The Eagle does not rise in the air so much for the purpose of pursuing its prey on the wing, as that it may be enabled to take an extensive survey of the country beneath; for its food does not consist so much of birds that pass most of their time in flight, as of those that live on or near the ground, and of such mammalia as it can vanquish. Buffon remarks, when speaking of the noble nature of this powerful bird, that the Eagle despises small animals, and disregards their insults; that he seldom devours the whole of his prey, but, like the lion, leaves the fragments to other animals; and, except when famishing with hunger, he disdains to feed on carrion. The astoundingly acute sight of the Eagle enables him to discern his prey at an immense distance; and, having perceived it, he darts down upon it with a swoop which there is no resisting.

It is well understood that the Eagle is

able to look stedfastly on the sun, and to sustain his most dazzling rays: which alone must give him a decided superiority over every other denizen of the air: this is accounted for by his being furnished with double eyelids, one of which may be shut while the other is open, so that the glaring light of any dazzling object may be rendered more easily supportable. The nest is composed of sticks, twigs, rushes, heath, &c., and is generally placed upon the jutting ledge of some inaccessible precipice; or in forests, near some lofty tree. The largest species of Eagles seldom lay more than two eggs, and the smallest never more than three.

THE IMPERIAL EAGLE. (*Aquila imperialis*.) This is the largest species of Eagle known, measuring three feet and a half from the tip of the bill to the end of the tail; and to it may be referred all the accounts of the ancients respecting the strength, courage, and magnanimity of these birds. Its colour above is rufous gray, barred with black, the black prevailing most on the wings: the head is strongly crested with long gray feathers, the two middle ones being five inches long; the tail is gray, barred and spotted with black, and tipped with rufous: the under parts of the bird are pale cinereous, very soft and downy; the beak and cere black; the feet and legs yellow. It is a native of South America, inhabiting the deep recesses of the forest; and has the reputation of being extremely bold and ferocious.

THE GOLDEN EAGLE. (*Aquila chrysaetos*.) This bird is the largest and noblest of the European Eagles; its length being three feet three inches, the extent of its wings seven feet six inches, and its weight from twelve to sixteen pounds. The bill is of a deep lead colour, with a yellow cere; eyes large, deep sunk, and covered by a projecting brow; the irides golden hazel-colour, bright and lustrous. The general colour of the plumage is deep brown, mixed with tawny on the head and neck, and the feathers on the back being finely shaded with a darker hue. The wings, when closed, reach to the end of the tail; the quill-feathers are chocolate-coloured, with white shafts; and the tail brown, the base being generally marked with irregular ash-coloured bars or blotches: the legs are yellow, short, and very strong, being three inches in circumference, and feathered to the very feet, which are covered with large scales, and armed with most formidable claws. It occurs in various mountainous parts of Europe and Asia, and also, though more rarely, in America: in Ireland, Scotland, and Wales, it has also occasionally been found. The cyrc or nest of the Golden Eagle is extremely large and strong, being composed of twigs and branches, interlaced and covered by layers of rushes, heath, &c., and built on the summits of rocks or lofty cliffs. The female lays two or, at most, three eggs, one of which is said to be generally unprolific. The longevity of this species is said to be great indeed, instances being quoted of its having survived more than a century.

THE RING-TAILED EAGLE (the *Falco fulvus* of Buffon), though described as a separate species by him, is no other than the young bird of one and two years of the preceding. Its colour is a deep brown, the base of the tail being distinguished by a white ring; the bill is of a dark horn-colour, the upper mandible, which is arched, hanging over the lower one about an inch, and having an angle or tooth on each side; and the feet are feathered to the toes. The breast is marked with white triangular spots in the middle of each feather: between the bill and the eyes there are spaces of bare skin of a dirty hue, thinly set with small black hairs: and the tail, which is of an equal length with the wings when closed, is white, except the tips of the feathers, which are black, or dark brown; and the coverts under the tail are a reddish brown or bay. The toes are very thick and strong, and covered with yellowish scales; and the talons, which are black and very powerful, bend almost into semicircular figures, and terminate in very sharp points.

"It is held," says Dr. Richardson, "by the aborigines of America, as it is by almost every other people, to be an emblem of might and courage, and the young Indian warrior glories in his Eagle plume as the most honourable ornament with which he can adorn himself. Its feathers are attached to the calumets, or smoking pipes, used by the Indians in the celebration of their solemn festivals, which has obtained for it the name of the Calumet Eagle. Indeed, so highly are these ornaments prized, that a warrior will often exchange a valuable horse for the tail feathers of a single eagle." He further observes that the mature British Golden Eagle has a darkish brown tail and wings, blackish-brown back, clouded with brownish-black, and a paler and brighter-brown head. The identity of the Ring-tails with the Golden Eagles may now be considered unquestionable, the observations of so many late ornithologists concurring to establish the fact. And though Dr. Richardson says that the Golden Eagle is seldom seen farther to the eastward than the Rocky Mountains, M. Audubon asserts that he has seen it on the coast of Labrador, and various other parts of the United States. It inhabits Russia, Iceland, and Germany, and is said to occur in Northern Africa and Asia Minor. It is also frequently met with in Scotland, and its northern and western islands; in Ireland also, though much less often; and occasionally even in the western counties of England.

THE ROYAL EAGLE (*Aquila regalis*) is a bird of great beauty, having an elegantly varied plumage and commanding attitudes; in fact, the account given of it by M. Sonnini, in his edition of Buffon's Natural History, would lead to the belief that it is much larger and more ferocious than any one of which we have a knowledge. His description of it is to this effect:—"The head is large, and furnished with a crest in form of a casque: the bill long; the eyes bright and piercing; the claws black, crooked, and of

the length of the middle finger: the back, wings, and tail are brown, spotted with black, and variegated with whitish or yellowish streaks; the belly white, the feathers being very soft, and equal in elegance to those of an egret. It flies with majestic rapidity, and such is the expanse of its wings, that it sometimes strikes and kills its prey with them before it touches it with its claws. Its strength is such as to enable it to tear in pieces in an instant the largest sheep; and it pursues, almost indiscriminately, wild animals; but its principal food consists of a particular kind of monkeys, called *Guaribas*, which it instantly kills, and devours with extraordinary voracity. Its general residence is on lofty mountains, and it builds its nest on the highest trees, employing for their construction the bones of the animals it has slaughtered, and some dry branches of trees, which it binds together with the ends of climbers. It is said to lay two or three eggs, which are white, spotted with reddish-brown. It is chiefly found about the borders of the river Amazon. Many virtues are attributed to its burnt feathers. Such is the account, with some slight abridgment, of the description given by Sonnini, and copied by Shaw; the whole resting on the authority of Don Laurent Alvarez Roxo de Postallitz, a Portuguese ecclesiastic at Brazil.

WEDGE-TAILED EAGLE. (*Aquila fucosa*.) This noble bird is the species of Eagle common to Australia, "being of course," as Mr. Gould observes, "more plentiful in such districts as are suited to its habits, and where the character of the country is congenial to the animals upon which it subsists." He further says, that although he has not yet seen it in any collection, either from the

WEDGE-TAILED EAGLE.—(*AQUILA FUCOSA*.)

northern portion of Australia or any other country, "in all probability it will hereafter be found to extend its range as far towards the tropics in the southern hemisphere as the Golden Eagle (*Aquila chrysaetos*) does in

the northern: the two birds being, in fact, beautiful analogues of each other in their respective habitats, and doubtless performing similar offices in the great scheme of creation." In courage, power, rapacity, and size, they are also very similar; but the lengthened and wedge-shaped form of its tail gives to the Australian bird a far more pleasing and elegant contour. One, but by no means the largest, of those which were killed by Mr. Gould, weighed nine pounds, and measured six feet eight inches from tip to tip of the opposite pinions. The Wedge-tailed Eagle frequents the interior portions of the country rather than the neighbourhood of the sea; preying indiscriminately on all the smaller species of Kangaroo which tenant the hills and plains; and whose retreats, from the wonderful acuteness of its vision, it descends while soaring and performing its graceful evolutions in the air. The enterprising ornithologist, from whose splendid work we have derived the foregoing information, goes on to say, that "its tremendous stoop and powerful grasp carry inevitable destruction to its victim, be it ever so large and formidable. The breeders of sheep find in this bird an enemy which commits extensive ravages among their lambs, and consequently in its turn it is persecuted unreluctantly by the shepherds of the stock-owners, who employ every artifice in their power to effect its extirpation, and in Van Diemen's Land considerable rewards are offered for the accomplishment of the same end." He adds, that "the tracts of untrodden ground and the vastness of the impenetrable forests will, however, for a long series of years to come, afford it an asylum, secure from the inroads of the destroying hand of man: still, with every one waging war upon it, its numbers must necessarily be considerably diminished." In the adult bird, the head, throat, and all the upper and under surface of the plumage is blackish brown, stained on the edges and extremities of many of the wing and tail feathers with pale brown; back and sides of the neck rusty-red; irides hazel; cere and space round the eye yellowish white; bill yellowish horn colour, the tip black; feet light yellow. The colour of the young birds is altogether lighter, and the tail is indistinctly barred near the extremity. The nests are of a very large size, built of sticks and boughs, nearly flat, and, placed on trees which from their vast height, are all but inaccessible to man. It appears that although the Wedge-tailed Eagles mostly feed on living prey, they do not scruple to feast on the carcass of a dead bullock when they find one, or refuse to devour carrion, though it may be almost in a state of putridity.

We lately saw three specimens of this very fierce Eagle in the Gardens of the Zoological Society. Their piercing eyes and enormous beaks clearly indicated their "will and power," while their restlessness was a convincing proof that they could ill brook captivity.

VULTURINE EAGLE. (*Aquila vulturina*.) The general colour of this species, which in

size is equal to the Golden Eagle, is a deep black, some of the feathers of the back having brownish edges: the bill is very strong, its tip yellow; the legs of a dirty yellow, and feathered for three quarters of their length: the tail rounded, and considerably shorter than the wings. It feeds principally on carrion, but will attack sheep, and devour them on the spot. Native of Caffraria.

CROWNED EAGLE. (*Aquila coronata*.) This species is about one-third less than the generality of Eagles, but of proportionate boldness and strength. It is a native of Africa, and is said to be principally seen in Guinea. The circles round the eyes are of a deep orange colour; the fore part of the head, the space round the eyes, and the throat, are covered with white feathers, with small black spots: the hinder part of the head and neck, the back and wings, are of a dark brown, the outer edges of the feathers being lighter: the ridge in the upper part, and the tips of some of the lesser covert-feathers of the wings, are white: the tail is brown, barred across with black, and on its under side appears of a dark and light ash-colour: the breast is of a reddish-brown, with large transverse black spots on the sides: the thighs and legs, down to the feet, are covered with white feathers, beautifully marked with round black spots. The feet and claws are very strong; the former covered with scales of a bright orange colour, and the latter being black. It takes its name from raising the feathers on the hinder part of the head in the form of a crest or crown.

THE SUPERN EAGLE (*Falco superbus*) inhabits the vast forests of Guiana, and is distinguished by a kind of pendent naked craw, like some of the vultures. From the tip of the bill to that of the tail is about twenty-five inches: the upper part of the head and the crest are brown: the back and wings brown, with a few transverse tawny bars: and the tail is alternately barred with black and pale brown: the sides of the neck are tawny; the throat and breast white; the abdomen white, with transverse black stripes, interrupted by the white ground-colour: the feathers of the thighs and legs are white, striped with black.

THE CHEELA EAGLE. (*Falco Cheela*.) This species is a native of India, where it is called Cheela. It is of a stout make, two feet long, and of a deep brown colour; but on each side of the head there is a mixture of white: the wing-coverts and thighs are marked with small white spots, and the tail is crossed in the middle by a white band: the bill is blue at the base, and black at the tip.

THE WHITE-TAILED EAGLE. (*Haliaetus albicilla*.) This bird inhabits all the northern parts of Europe, and is found in Scotland and other parts of Great Britain. The beak, cere, and eyes are of a pale yellow; the sides of the head and neck a pale ash, mixed with reddish-brown: general colour of the plumage brown, darkest on the upper part of the head, neck, and back: quill feathers

very dark; breast irregularly marked with white spots; tail white; legs of a bright yellow, and claws black. It is strong, and very ferocious. It usually lays two or three eggs, building its nest upon lofty trees.

THE WHITE-HEADED SEA EAGLE. (*Haliaetus leucocephalus*.) This distinguished bird is about the size of the Golden Eagle, to which it bears a considerable resemblance; it is, however, of a lighter colour, and the legs are only feathered a little way below the knees. The bill is large, much hooked, and bluish. A row of strong bristly feathers hangs down from under its lower mandible, whence it has sometimes been termed the Bearded

AMERICAN, OR WHITE HEADED SEA EAGLE
(*HALIAETUS LEUCOCEPHALUS*.)

Eagle. It preys chiefly on fish, which it seizes by darting down upon them while swimming near the surface: it also occasionally preys on birds and other animals. The American variety is superior in size to the European; frequenting the neighbourhood of the sea, and the shores and cliffs of lakes and large rivers, which localities he prefers, from his great partiality for fish. Wilson, the American ornithologist, thus picturesquely describes this powerful bird:—"Elevated upon a high, dead limb of some gigantic tree, that commands a wide view of the neighbouring shore and ocean, he seems calmly to contemplate the motions of the various feathered tribes that pursue their busy avocations below—the snow-white gulls slowly winnowing the air; the busy triage, coursing along the sands; trains of ducks, steaming over the surface; silent and watchful cranes, intent and wading; clamorous crows, and all the winged multitudes that subsist by the bounty of this vast liquid magazine of nature. High over all these hovers one, whose action instantly arrests all the Eagle's attention. He knows him to be the fish-hawk, settling over some devoted victim of the deep. His eye kindles at the sight, and, balancing himself with half-opened wings on the branch, he watches the result. Down, rapid as an arrow from heaven, descends the distant object of his attention, the roar of its wings reaching the ear as it disappears in the deep, making the surges foam around. At this moment the eager looks of the Eagle are all ardent, and, levelling his neck for flight, he sees the fish-hawk once more emerging, struggling with his prey, and mounting in the air with screams of exultation. There is a signal for our hero, who, launching into the air, instantly gives chase; soon gulls on the fish-hawk; each exerts his utmost to

mount above the other, displaying in the rencontre the most elegant and sublime aerial evolutions. The unincumbered Eagle rapidly advances, and is just on the point of reaching his opponent, when, with a sudden scream, probably of despair and honest excretion, the latter drops his fish: the Eagle, poising himself for a moment, as if to take a more certain aim, descends like a whirlwind, snatches it in his grasp, ere it reaches the water, and bears it silently away to the woods." When this bird has fasted for some time, its appetite is extremely voracious and indiscriminate: even the most putrid carrion, when nothing better can be had, is acceptable. The nest of this species, formed of large sticks, sods, moss, hay, &c., is usually found in a lofty tree, in a swamp or morass; and as it is increased and repaired every season, becomes of great size. Fish are daily carried to the nest in such numbers, that they sometimes lie scattered round the tree; and the odour is very offensive for a considerable distance round it.

EAGLE-OWL. (*Bubo*). [See OWL.]

EAR-SHELL. (*Haliotis*). A genus of univalve Mollusca, the shell being of a flattened shape, perforated with small holes on one side, and somewhat resembling the human ear, its base being characterised by a very wide mouth or aperture, the largest in any shell except the Patella or Limpet. This genus sometimes yields small pearls, the rudiments of which are frequently seen in those shells which have not brought them to perfection. The outside is generally rough, worn, or covered with marine substances; the inside presents the same enamelled appearance as mother-of-pearl, and exhibits the most beautiful colours. The holes with which the shell is perforated are for the passage of the lobes of the animal's mantle, and are made at regular intervals as it increases in size: when, however, a new one is formed, the one nearest the spire is closed up. The head of the animal is

CHANNELLED EAR-SHELL.
(*HALIOTIS CANALICULATA*.)

large, having two long round tentacula, with eyes at the base on footstalks; foot very large, having the margin fringed all round. In its state of rest, it is able to adhere with such tenacity to the substance it is fixed

upon as to be removed with great difficulty, although it can detach itself with ease. It is always found near the surface of the water. There are several species of this shell: the one termed the Great Ear-shell is five inches long and nearly three wide; its shape is an irregular oval, the end where the spiral turn is placed being the largest. It is chiefly found in the East Indies.

EARTHWORM. (*Lumbricus*). An Annelide, of which there are doubtless many species; characterised by a long cylindrical body, divided by transverse furrows into a great number of rings, and by a mouth without teeth: they have neither eyes, tentacles, gills, nor cirtih. The common well-known species (*Lumbricus terrestris*) attains nearly a foot in length, and is composed of upwards of one hundred and twenty rings. They are very abundant, piercing and traversing the ground in every direction, subsisting on roots, woody fibres, animal matter, and other organized substances. It is well known that they swallow earthly matter, and that having separated the serviceable portion, they eject at the mouth of their burrows the remainder in little intestine-shaped heaps, or worm-casts.

Though a small and despised creature, the Earthworm is a most important one in the operations of nature. When it is boring, it insinuates its pointed head between, the particles of the earth, amongst which it penetrates like a wedge: and in this position the anterior part of the body is fixed by the spines, of which there are four pairs on each segment: the hinder parts are then drawn forwards by a shortening of the body, which swells out the anterior segments, and forcibly dilates the passage into which the head has been already thrust. By the frequent repetition of this process, the little animal more easily permeates hard substances than could be possibly conceived; and by the united labours of myriads, the earth is lightened, and vegetation thereby wonderfully assisted. Mr. Knapp, in his 'Journal of a Naturalist,' thus speaks of the Earthworm:—"This animal, destined to be the natural manurer of the soil, and the ready indicator of an improved staple, consumes on the surface of the ground, where they soon would be injurious, the softer parts of decayed vegetable matters, and conveys with the soil the more woody fibres, where they moulder, and become reduced to a simple nutriment, fitting for living vegetation. The parts consumed by them are soon returned to the surface, whence, dissolved by frosts and scattered by rains, they circulate again in the plants of the soil—death still producing life." Thus eminently serviceable as the worm is, it yet becomes the prey of various orders of the animal creation, and perhaps is a solitary example of an individual race being subjected to universal destruction. The very emmet seizes it when disabled, and bears it away as its prize: it constitutes throughout the year the food of many birds; fishes devour it greedily; the hedgehog eats it; the mole pursues it unceasingly in the

pastures, along the moist bottoms of ditches, and hurrows after it through the hanks of hedges, to which it retires in dry seasons. Secured as the worm appears to be by its residence in the earth from the capture of creatures inhabiting a different element, yet many aquatic animals seem well acquainted with it, and prey on it as a natural food, whenever it falls in their way; frogs eat it; and even the great water-beetle (*Dytiscus marginalis*) I have known to seize it when the bait of the angler, and it has been drawn up by the hook. Yet, notwithstanding this prodigious destruction of the animal, its increase is fully commensurate to its consumption, as if ordained the appointed food of all."

In White's History of Selborne the valuable services of the Earthworm are detailed at great length, and with that writer's accustomed perspicacity. Charles Darwin, F. R. S., has made many interesting observations, which have been thus stated from his published researches:—"The hurrowing of Earthworms is a process exceedingly useful to the gardener and agriculturist; and these animals are far more beneficial to man in this way, than they are injurious by devouring the vegetables set in the soil. They give a kind of under tillage to the land, performing the same below ground that the spade does above for the garden, and the plough for arable land; and loosening the earth, so as to render it permeable to air and water. It has been shown, too, that they will even add to the depth of soil; covering barren tracts with a layer of productive mould. Thus, in fields which have been overspread with lime, burnt marl, or cinders, these substances are in time covered with finely-divided soil, well adapted to the support of vegetation. That this result, which is commonly attributed by the farmers to the 'working-down' of the materials in question, is really due to the action of the Earthworms, appears from the fact, that, in the soil thus formed, large numbers of worm-casts may be distinguished. These are produced by the digestive process of the worms; which take into their intestinal canal a large quantity of the soil through which they burrow, extract from it the greater part of the vegetable matter it may contain, and reject the rest in a finely divided state. In this manner, a field, manured with marl, has been covered, in the course of eighty years, with a bed of earth averaging thirteen inches in thickness."

"It is commonly supposed," says Dr. Carpenter, "that the Earthworm may be multiplied by the division of its body into two pieces, each of which will continue to live. This does not, however, appear to be the case with the common species. If it is divided across the middle, when in motion, each part will continue to move for a time; but only the piece which bears the head will be found alive after a few hours. This forms a new tail: and soon shows little sign of injury. But if the division be made near the head, the body will remain alive, and will renew the head;

and the head, with its few attached segments, will die. There appears, however, to be some species, in which this reproductive power is sufficiently great to produce a new head and body from even a small portion of the original; so that above twenty individuals have been produced in this manner by the division of a single one into as many parts."

EARWIG. (*Forficula*.) A genus of Dermapterous insects. The common Earwig, generally called in Scotland GOLLACH (*Forficula auricularia*), is about three quarters of an inch in length, and has a somewhat flattened body; the wings being folded under very short and truncated elytra or wing-cases, and the extremity of the abdomen armed with a horny forceps. When alarmed, the insect elevates the abdomen, and opens these forceps, in order to defend itself from the attack of its enemies. Though not produced quite perfect from the egg, the Earwig requires but a very small change before it arrives at that state which fits it for flight and

EARWIG.—(*FORFICULA AURICULARIA*.)

generation. Its natural functions are never suspended; from the instant it leaves the egg, it continues to eat, move, leap, and pursue its prey; and a skin which inclosed a part of its body and limbs bursts behind, and gives full play to a set of wings with which it flies in pursuit of its mate. The places in which they are found are chiefly damp and cool situations, under stones and the bark of trees, among chests and boxes which have been long undisturbed, and in similar haunts. They seem to be as timid as hares, and when disturbed run into the nearest hole, satisfied, like the quadrupeds above named, if they can get their heads under cover, and thus exclude the sight of danger, even when their bodies are fully exposed. Hence, it often happens that they will be found with their heads buried in the bottom of flowers, their forked tails sticking up among the stamens and pistils, so that they might escape the notice of any one but a botanist or an entomologist.

Mr. Newman gives the following interesting description of this insect and its habits:—"The Earwig is one of our most common insects; it is well known to every one, and is very generally an object of unconquerable dislike; the forceps at its tail, and the threatening manner in which these are turned over its back, to pinch anything of which it is afraid, render it peculiarly disgusting. The fore wings of the Earwig are

square, short, leathery pieces, which cover but a very small portion of the body: the insect is incapable of bending or folding them in any direction, or of using them as organs of flight. The hind wings are quite different from the fore wings; they are folded into a very small compass, and covered by the fore wings, except a small portion which protrudes from beneath them; and, when examined in this position, appear totally useless as organs of flight. When unfolded, the hind wings are remarkably beautiful; they are of ample size, perfectly transparent, displaying prismatic colours when moved in the light; and are intersected by veins, which radiate from near the centre to the margin. The shape of these wings, when fully opened, is nearly that of the human ear; and from this circumstance it seems highly probable that the original name of this insect was *Earwing*. It derives its present name from its supposed habit of insinuating itself into the ears of persons who incautiously lie down and sleep on the grass, &c.: a supposition, if not entirely groundless, unsupported by any well authenticated instances.]

"*Earwigs* subsist principally on the leaves and flowers of plants, and on fruit; and they are entirely nocturnal insects, retiring by day into dark crevices and corners, where they are scarcely from observation. The rapidity with which they devour the petals of a flower is remarkable; they clasp the edge of a petal in their fore legs, and then, stretching out their head as far as possible, bite out a mouthful; then another mouthful nearer, and so on till the head is brought to the fore-legs. This mode of eating is exactly that which is practised by the caterpillars of butterflies and moths: the part of a leaf or petal is eaten out in a semicircular form, and the head is thrust out to the extreme part, after a series of mouthfuls. Pinks, carnations, and dahlias, very frequently lose all their beauty from the voracity of these insects. When the time of breeding has arrived, which is generally in the autumn, the female retires for protection to the cracks in the bark of old trees, or the interstices of weather-boarding, or under heavy stones on the ground: here she commences laying her eggs. The eggs are usually from twenty to fifty in number: when the female has finished laying them, she does not forsake them, as is the habit of other insects, but sits on them in the manner of a hen, until they are hatched. When the little ones leave the shell, they are very perceptible; larger than the eggs which contained them. They precisely resemble the parent in structure and habit, except that they are without wings; they also differ in colour, being perfectly white. The care of the mother does not cease with the hatching of the eggs: the young ones run after her wherever she moves, and she continues to sit on them and brood over them with the greatest affection for many days. If the young ones are disturbed or scattered, or if the parent is taken away from them, she will, on the first opportunity, collect them again, and brood over them as carefully as before, allowing

them to push her about, and cautiously moving one foot after another, for fear of hurting them. If the young ones are fed until the mother's care for them has ceased, does not appear to have been ascertained; for it is not until they are nearly half grown that they are seen feeding on vegetables with the rest."

A remarkable fact, in relation to the *Earwig*, is its great abundance at particular times, and its subsequent rarity. From the observations of entomologists, it has been proved that these insects migrate in considerable flocks, selecting the evening for their excursions. It is common with gardeners to hang up, among the flowers and fruit-trees subject to their attacks, and also to place on the ground, pieces of hollow reeds, lobster-claws, and the like, which offer enticing places of retreat for these insects on the approach of daylight, and by means thereof great numbers of them are obtained in the morning. Poultry are very fond of *Earwigs*. There are many exotic species of this genus, some of them with remarkably elongated forceps.

EBURNA. A genus of marine Mollusca found in the Indian and Chinese seas, inhabiting an oval, thick, smooth, umbilicated shell. The *Eburnæ* in some respects resemble the *Buccina*; from which, however, they are essentially different. The head of the animal is furnished with a

EBURNA SPIRATA.

proboscis, and two tentacula having eyes in the middle; foot short; spine angulated and acute; aperture oval, terminating anteriorly in a canal, posteriorly in a groove; outer lip slightly thickened with an anterior notch, which terminates a spiral fold surrounding the body whorl; umbilicus generally covered by the thickened columellar lip.

ECHIDNA, or PORCUPINE ANTERATER. (*Echidna hystrix*.) This curious animal is a native of Australia, and is a striking instance of that beautiful gradation, so frequently observed in the animal kingdom, by which creatures of one tribe or genus approach to those of a very different one. It has the external coating and general appearance of the Porcupine, with the mouth and peculiar generic characters of the anteaters. It is about a foot in length: the upper parts of the body and tail are thickly coated with strong and very sharp spines, of a yellowish white with black tips, and thicker in proportion to their length than those of a porcupine. The head, legs, and under parts of the body are of a deep brown, and thickly set with bristly hair; the tail is very short, and covered with spines pointing perpen-

dicularly upwards. The snout is long and tubular, the mouth small, and the tongue long and lumbriciform, as in other Ant-eaters. The legs are very short and thick; and are each furnished with five rounded,

PORCUPINE ECHIDNA.—(ECHIDNA HYSTRIX.)

broad toes: on the fore feet are five very strong, long, and blunt claws; but on the hind feet there are only four claws, the thumb being destitute of a claw: the first claw on the hind feet is extremely long, rather curved, and sharp pointed; the next shorter, but of similar appearance; the two remaining ones far shorter, and blunt: it has great strength, and burrows with wonderful celerity.

At a meeting of the Zoological Society, July 22, 1845, Professor Owen communicated his observations on the living *Echidna* exhibited at the Menagerie of the Society in May preceeding. The animal when received at the Gardens was active and apparently in sound health. It was placed in a large but shallow box, with a deep layer of sand on one half of the bottom; the top covered with close cross-bars. The animal manifested more vivacity than might have been expected from a quadruped which, in the proportions of its limbs to its body, as well as in its internal organization, makes the nearest approach, after the Ornithorhynchus, to the Reptilia. In the act of walking, which was a kind of waddling gait, the body was alternately bent from one side to the other, the belly was lifted entirely off the ground, and the legs, though not so perpendicular as in higher mammalia, were less bent outwards than in lizards. The broad and short fore paws were turned rather inwards; the hind feet had their claws bent outwards and backwards, resting on the inner border of the sole. The animal was a male; and the tarsal spur, smaller and sharper than in the Ornithorhynchus, projected backwards and outwards, almost hidden by the surrounding coarse and close hair. The small eyes gleamed clear and dark; the ball was scarcely retracted when the animal winked, which it did frequently. It commenced an active exploration of its prison soon after it was encaged: the first instinctive action was to seek its ordinary shelter in the earth, and it turned up the sand rapidly by throwing it aside with strong strokes of its powerful fossorial paws, and repeating the act in many places, until it had assured itself that the same hard impenetrable bottom everywhere opposed its progress downwards. The animal then began to explore every fissure and cranny, poking its long and slender nose into each crevice and hole, and through the interspaces of the cross-bars above. To reach

these it had to raise itself almost upright, and often overbalanced itself, falling on its back, and recovering its legs by performing a summerset. I watched these attempts of the animal to escape for more than an hour, and it was not till it had got experience of the strength of its prison, that the *Echidna* began to notice the food which had been placed there. This consisted of a saucer of bread and milk and some meal-worms. The milk was sucked or rather licked in by rapid protrusion and retraction of the long red cylindrical tongue. The tongue came more than once in contact with the larvae, which were sometimes rolled over by it, but no attempt was made to swallow them. The *Echidna* offered little resistance when seized by the hind-leg and lifted off the ground, and made not the slightest demonstration of defending himself by striking with his hind spurs: the only action when irritated was to roll itself into a ball like a hedgehog—the bristles being then erect.—*Ann. Nat. Hist.*

ECHIMYS; ECHIMYNA. The name of a genus and subfamily of Rodents, containing the genus *Echimys* or *Lonchoceros*; a largeish spiny-haired rat-like animal with a long tail; it is a native of South America. The genus *Octodon*, an arboreal type found in Chili; and *Aulacodus* or Ground Pig, from South Africa—also belong to this subfamily.

ECHINEIS. A genus of fish remarkable for a series of suckers on the top of the head. [See REMORA.]

ECHINODERMATA. The name given to an extensive class of Invertebrata of the division **RADIATA**, comprising all those which have a hard coriaceous integument, which in some species is covered with sharp spines or prickles, like those of the hedgehog; a digestive and vascular system; and a sort of radiating nerves. They are all marine animals, possessing the power of locomotion; the sexes are distinct; and the young are produced from ova. "In this group," as Mr. Patterson observes, "we find animals of extremely dissimilar appearance associated together. One species is attached, for a certain period, to a stem, and resembles a polype, with its waving and sensitive arms. In the common star-fish, or 'five-fingers,' we have the arms radiating from a common centre. In the sea-urchins there are no arms, and the form of the body is globular,

ECHINUS ORENULARIS.

and, passing over some intermediate gradations of figure, we reach creatures which in external aspect, resemble worms, and have

even been classed as such. At one extremity of the range, the Echinodermata remind us of polypes—creatures of inferior organization; at the other extremity, they approach the annulose animals, whose structure is of a higher grade. Those occupying the centre of the group may be regarded, therefore, as the types or representatives of the class." [See ASTERIAS; ECHINUS; ENCRINITE; HOLOTHURIA; OPHIURINÆ; and ALTERNATION OF GENERATION in SUPPLEMENT.]

ECHINOPS. A singular genus of the Shrew tribe, allied to the *Tenrec*, and a native of Madagascar and the Mauritius; one species, *E. Telfairii*, is known.

ECHINORHYNCHUS. [See SUPPL.]

ECHINUS. The generic name of the SEA-URCHINS, or SEA-EGGS, which constitute the type of the class *Echinodermata*, or certain invertebrate animals, which have a crustaceous or coriaceous integument, most commonly armed with tubercles or spines. They are all inhabitants of the sea; and many of them have often been found in a fossil state. The spines are connected with the outer skin by very strong ligaments, and are the instruments of motion. They are generally armed with five sharp teeth; and the pores are furnished with a retractile tentacle or feeler to each, by which the animal affixes itself to any object, and stops its motion. The species most esteemed as an esculent, and thence denominated *Echinus esculentus*, is subglobular; with ten avenues of

EDIBLE SEA UROHIN.
(ECHINUS ESCULENTUS.)

pores, the spaces between covered with small tubercles supporting the spines; body reddish or yellowish; spines short, of a violet colour; losing their colour and falling off the dead animal; pores in about three rows; tubercles surrounded with a circle of less ones; vent closed with a coriaceous membrane covered with spines. Echini of this sort constitute no small part of the food of the poor in many countries, and some species are reckoned excellent. In ancient times they were accounted very delicious, being usually dressed with vinegar, honied wine, parsley, and mint; it is recorded that they composed the principal dish at the famous supper of Lentulus, when he was made Flamen Martialis, or Priest of Mars. Our cut exhibits one half of the surface denuded of its spines to show their mode of insertion. Fossil Echinide, in almost incredible num-

bers, are to be traced through all the formations, from the epoch of the transition series to the present time; many of them being found in our own chalky or silty soils. The *Echinus vulgaris*, so perpetually found in a fossil state, is not now traced in a living state: in make it is orbicular; with ten avenues, two of them always near each other.

EDENTATA. The name given to an order of quadrupeds, which although it includes many animals differing from each other widely in habits, and also in certain points of structure, yet agree in so many essential characters, and are connected together by so many intermediate links, as to require being associated in the same group. They all agree in the absence of teeth in the front of the jaws; all resemble each other in the great claws which encompass the ends of their toes; and they are all distinguished by a certain slowness, or want of activity, obviously arising from the peculiar organization of their limbs. The armour-clad, insectivorous *Armadillos*, of South America; the tree-inhabiting *Sloths*, and hairy toothless *Ant-eaters*, of the same continent; the gigantic *Megatherium*, which formerly inhabited it; and the *Mamie*, whose lizard-like body, defended by an impenetrable coat of mail, excites our wonder—all belong to the order *EDENTATA*; which constitute the last group of ungulate animals, and are severally described in the course of this work.

EEL. (*Anguilla*.) The Eel, which in a natural arrangement of the animal world may be considered as in some degree connecting the fish and serpent tribes, is a native of almost all the waters of the ancient continent, frequenting not only rivers but stagnant waters; and occasionally salt marshes and lakes. Its general appearance is so well known, and so unlike most other fishes, as to require but a slight description: we should observe, however, that though the external form of the body resembles the snake, the important internal organs, and the character of the skeleton, are decidedly different. The Eel is distinguished by its uniform colours, but more particularly by the peculiar elongation of the lower jaw, which advances to some distance beyond the

EEL—(ANGUILLA VULGARIS.)

upper: the head is small and pointed; the eyes are small, round, and covered by a transparent skin, united with the common integument of the body; the mouth is small, and both jaws and palate are beset with several rows of small sharp teeth: the orifices of the gills are very small, of a lunated shape, and are seated close to the pectoral fins, which are small, and of an ovate shape:

the back-fin commences at some distance beyond the head, and is continued into the tail-fin, which is also united with the vent-fin. The general colour of the Eel is olive-brown on the back, and silvery on the sides and beneath; the fins are slightly tinged with violet, and sometimes margined with pale red; it is, however, sometimes seen of a very dark colour, with scarce any silvery tinge, and sometimes yellowish or greenish: those being the most beautiful which inhabit the clearest waters. The skin of the Eel is proverbially slippery, being furnished with a large proportion of mucus: it is also furnished with small deeply-imbedded scales, which are not easily visible in the living animal, but are very conspicuous in the dried skin. Fresh-water eels, inhabiting running streams with gravelly bottoms, are said to be uniformly white upon the belly, and infinitely more delicate than those of muddy waters, which possess a peculiar smell and flavour, by no means agreeable. In the choice of its food the Eel is far from being cleanly, feeding indiscriminately upon all kinds of small fish, and decayed animal matter: they are, however, a most valuable description of fish: their flesh is excellent as food, being highly nutritious, though sometimes too oily for weak stomachs. They are very prolific, hardy, and very easily preserved: they inhabit almost all our rivers, lakes, and ponds; and as they are in great esteem for the table, the consumption in our large cities is very considerable. Few animals are more tenacious of life; they continue to move for a long time even when deprived of the head and skin, preserving the muscular irritability for many hours after death.

The Eel is viviparous, producing its numerous young; during the decline of summer: these at their first exclusion are very small. Very gross errors on this subject were formerly indulged in; but it appears that both eggs and ready-formed young are occasionally observed in the same individuals, as is known to be the case also with several other animals. As Mr. Yarrell observes, "during the cold months of the year Eels remain imbedded in mud; and large quantities are frequently taken by eel-spears in the soft soils and harbours and banks of rivers, from which the tide recedes, and leaves the surface exposed for several hours every day. The Eels bury themselves twelve or sixteen inches deep, near the edge of the navigable channel, and generally near some of the many land-drains, the water of which continues to run in its course over the mud into the channel during the whole time the tide is out. In Somersetshire the people know how to find the holes in the banks of rivers in which Eels are laid up, by the hoarfrost not lying over them as it does elsewhere, and dig them out in heaps. The practice of searching for Eels in mud in cold weather is not confined to this country." Some marvellous accounts are on record of the migration of Eels from one river to another, over intervening portions of dry land. On this subject the same author thus expresses himself: "There is no doubt that

Eels occasionally quit the water, and when grass meadows are wet from dew, or other causes, travel during the night over the moist surface in search of frogs or other suitable food, or to change their situation. Some ponds continually produce Eels, though the owners of these ponds are most desirous of keeping the water free from Eels, from a knowledge of their destructive habits towards the spawn and fry of other fishes. Other ponds into which Eels have been constantly introduced are obnoxious to them from some quality in the water; and they are known to leave such places during the night, and have been found on their passage to other retreats." The general size of the Eel is from two to three feet, but it is said that it sometimes, though very rarely, attains to the length of six feet, and to the weight of twenty pounds. It is a fish of slow growth, and is supposed to live to a very considerable age; and is attacked by a great many species of intestinal worms.

The CONGER EEL (*Anguilla conger*), in its general appearance is so nearly allied to the common Eel, that on a cursory view it might at first be considered as the same species; it, however, differs materially from it in size, being sometimes ten feet in length, as thick as a man's thigh, and weighing 100 lbs.: it is also in general of a darker colour on the upper part, and of a lighter hue beneath: there is also on the sides a straight, white, broadish line, seemingly composed of a double row of points, which reaches from the head to the tail. The Conger resides generally in the sea, and is only an occasional visitant of fresh waters. In the winter it is supposed to imbed itself under the soft mud, and to lie in an inactive state; but on the approach of spring it emerges from its concealment, and visits the mouths of rivers.

CONGER EEL—(*ANGUILLA CONGER*.)

The able naturalist above quoted informs his readers that "the principal fishery for Congers in this country is on the Cornish coast; where, according to Mr. Couch, it is not uncommon for a boat with three men to bring on shore from five hundred weight to two tons, the fishing being performed during the night; for this fish will not readily take a bait by day, and even on moonlight nights it is more shy than when in the dark, except in deep water. The most usual bait with the Cornish fishermen is a pilchard. The Congers that keep among rocks hide themselves in crevices, where they are not unfrequently left by the retiring tide; but in situations free from rocks, Congers hide themselves by burrowing in the ground. The flesh is not in much estimation, but meets a ready sale at a low price among the lower classes. The adult fish is most re-

raculous, not sparing even those of its own species. From the stomach of a specimen weighing twenty-five pounds, I took three common Dabs, and a young Conger of three feet in length. The power of the jaws in this fish is very great: in the stomach of small specimens examined on the coast, I have found the young testaceous coverings of our shell-fish comminuted to fragments. They are often tempted by the crustacea entrapped in the lobster-pots to enter those decoys in order to feed on them, and are thus frequently captured."

EFT. [See **NEWT.**]

EGG-BIRD. The name given to some species of web-footed birds belonging to the *Laridae* family. [See **TERN.**]

EGGER (MOTH). A name given by collectors to the species of Moths, of the genera *Lasiocampa* and *Eriogaster*.

EGRET. [See **HERON.**]

EIDER DUCK. (*Somateria mollissima*.) This valuable species of wild duck is of a size between the tame duck and the goose, measuring about two feet in length. The head is large; the middle of the neck small, with the lower part of it spread out very broad, so as to form a hollow between the shoulders. The bill is of a dirty green or

EIDER DUCK,
(*SOMATERIA MOLLISSIMA*.)

harn colour, and the upper mandible forked in a singular manner towards each eye, and covered with white feathers on the sides as far forward as the nostrils. The upper part of the head is of a soft velvet black, divided behind by a dull white stroke: the feathers, from the nape of the neck to the throat, are pulled out, and look as if they had been clipped off at the lower ends. The cheeks, chin, upper part of the neck, the back, and lesser wing-coverts, are white; the scapulars, dirty white; bastard wings, and primary quills, brown; secondaries, and greater coverts, darker brown; the front part of the neck, to the breast, is of a buff colour; the breast, belly, rump, and tail-coverts are of a deep sooty black; tail feathers hoary brown; legs short, and yellow; webs and nails dusky. The full-grown male weighs from six to seven pounds; the female only between five and six. Her shape is nearly the same; but her plumage is quite different, the ground colour being of a reddish brown, crossed with wavy black lines: the wings

are crossed with two bars of white; quills dark; the upper part of the neck marked with dusky streaks; and the belly is deep brown, spotted ob-ovately with black.

This highly useful and valuable species is a native of the frozen regions of the north: it is extremely abundant in Iceland, Lapland, Greenland, and Spitzbergen, on the shores of Baffin's and Hudson's Bays, &c.; it is also very numerous in the Hebrides and the Orkades, but becomes rare as we advance to the south. The female lays five or six pale greenish-olive eggs in a nest composed of marine plants, and thickly lined with a beautiful down of most exquisite fineness, which is highly esteemed for its excessive lightness, elasticity, and useful qualities. The nest is usually formed on small islands, not far from the shore. As long as the female is sitting, the male continues on watch at no great distance; but as soon as the young are hatched he leaves them; the mother, however, remains with them a considerable time afterwards, and is said to assist them out of the nest almost as soon as they creep from the eggs, and proceeding to the shore, they crawl after her; when she arrives at the water's edge, she takes them on her back, and swims a few yards with them; she then dives, and the young being left floating on the surface, they are obliged to take care of themselves.

The manner in which the eider down is taken is as follows:—When the collectors come to the nest, they carefully remove the female, and take away the superfluous down and eggs; after which they replace her. She then begins to lay afresh, and again has recourse to the down on her body to cover her eggs; and in the event of her own stock being exhausted, which is not unfrequently the case, she is now assisted by the male in furnishing the requisite quantity: even this is frequently taken away, when the birds proceed to furnish another supply, both of eggs and down; but if the cruel robbery be repeated again, they immediately abandon the place. One female generally yields about half a pound of down, which is worth about two dollars. This down, from its superior warmth, lightness, and elasticity, is preferred by the luxurious to every other article for beds and coverlets; and from the great demand for it, those districts in Norway and Iceland, where these birds abound, are regarded as the most valuable property, and are guarded with the greatest vigilance. As found in commerce, this down is in balls of the size of a man's fist, and weighing from three to four pounds. It is so fine and elastic, that when a ball is opened, and the down cautiously held near the fire to expand, it will completely fill a quilt five feet square; but it is worthy of observation that although the eider down taken from the nests is so excellent, the down of dead birds is little esteemed, from having lost its elasticity.

Eider Ducks associate in flocks, generally in deep water, diving to great depth for shell-fish, which constitute their principal food. They frequently retire to the rocky shores to rest, particularly on the appearance of an approaching storm. The Greenlanders

kill them with darts, pursuing them in their little boats, watching their course by the air bubbles when they dive, and always striking at them when they rise to the surface wearied. Their flesh is eaten by the Greenlanders, but it tastes strongly of fish; the eggs, however, are much esteemed. The female lays from six to eight eggs, in a rock-built nest, lined with her own exquisite down; but the eggs and the down are both frequently obtained at the hazard of life by people let down by ropes from craggy steep. The skin, taken off, feathers and all, are used by the inhabitants for their under garments. It appears that all the attempts which have been made to domesticate these birds have been unsuccessful.

Another species, called the KING EIDER, (*Somateria spectabilis* of systematic writers), not much unlike the preceding, inhabits the same coasts. Its beak, wattles, and legs are of deep vermilion: a straight band of velvety black surrounds the base of the upper mandible of the beak; and there is a similar double band which becomes spear-shaped on the throat: the top and back of the head are of a fusc bluish-grey; the cheeks are a brilliant sea-green; the neck, wing-coverts, and upper part of the back, are pure white: the scapulars, lower part of the back, wings, tail, and all the under parts of the body are deep black. The entire plumage of the female is brown.

ELAND. The largest species of Antelope found at the Cape of Good Hope, and in the southernmost parts of Africa generally. [See BOSELAPHAS in SUPPLEMENT.]

ELATER: ELATERIDÆ. A genus and family of Coleopterous insects, having setaceous antennæ; but whose leading character is a strong spine situated beneath the thorax, which fits at pleasure into a small cavity on the upper part of the abdomen; thus enabling the insect, when laid on its back, to spring up with great force and agility, in order to regain its natural position. There are various species of these beetles; but few of the European species are comparable in point of size to such as are natives of the tropics.

The largest, and one of the most remarkable, is the **ELATER FLABELLICORNIS**, which is two inches and a half long, and of a uniform brown colour: it differs from the rest in having very strongly pectinated antennæ, the divisions of which, forming a kind of fan on the upper part of each, are nearly a quarter of an inch in length. It is met with in many parts of Asia and Africa.

A species, still more remarkable than the preceding, is the *Pyrophorus noctilucus*, called in South America *Cocuyas*. It is about an inch and a half long, of a brown colour, and has a smooth, yellow, semi-transparent spot on each side of the thorax; these spots being, like those on the abdomen of the glowworm, highly luminous in the dark: in short, it is

one of the most brilliant of the Fire-flies which inhabit South America and the West India islands. It is asserted that a person may with great ease read the smallest print by the light of one of these insects held between the fingers, and gradually moved along the lines, with the luminous spots above the letters; but if eight or ten of them be put into a phial, the light will be suffi-

FIRE-FLY ELATER.
(*PYROPHORUS NOCTILUCUS*.)

ciently great to admit of writing by it. Oviedo says, that the Indians travel in the night with these insects fixed to their hands and feet; and that they spin, weave, paint, dance, &c., by their light. In Prescott's "Conquest of Mexico," vol. ii. p. 261, we are told that in 1520, when the Spaniards visited that country, "the air was filled with the 'cocuyos,' a species of large beetle which emits an intense phosphoric light from its body, strong enough to enable one to read by it. These wandering fires, seen in the darkness of the night, were converted, by the excited imaginations of the besieged, into an army with matchlocks!" Such is the report of an eye-witness. (Bernal Diaz, *Hist. de la Conquista*, cap. 122.) Several others might be mentioned of inferior size, one of which it may be necessary to describe; this is the *Elater oculatus*, which is of a dark brown colour, and somewhat smaller than the preceding; distinguished by the thorax being marked on each side by a large, oval, jet black spot, surrounded by a white margin. It is common in North America.

Such species of the Elater as are natives of this country are much smaller than the exotic ones above mentioned, and but rarely distinguished by any peculiar brilliancy.

The larvae or grubs of the Elaters live upon wood and roots, and are often very injurious to vegetation. Some are confined to old or decaying trees, others devour the roots of herbaceous plants, and are called *wire-worms*, from their sleekness and uncommon hardness. The English wire-worm is said to live, in its feeding or larva state, not less than five years; during the greater part of which time it is supported by devouring the roots of wheat, rye, oats, and grass, annually causing a large diminution of the produce, and sometimes destroying whole crops. It is said to be particularly injurious in gardens recently converted from pasture lands; and the method adopted for alluring and capturing these grubs consists in strewing sliced potatoes or turnips in rows through the garden or field; women

UNDER SIDE
OF AN
ELATER.

and boys are employed to examine the slices every morning, and collect the insects which readily come to feed upon the bait. Some of these destructive insects are long, slender, worm-like grubs, closely resembling the common meal-worm; nearly cylindrical, with a hard and smooth skin, of a buff or brownish yellow colour, the head and tail only being a little darker; each of the first three rings provided with a pair of short legs, and a short retractile wart or prop-leg, serving to support the extremity of the body, and prevent it from trailing on the ground. Other grubs of *Elaters* differ from the foregoing in being proportionally broader, not cylindrical, but somewhat flattened. Such are mostly wood-eaters.

After their last transformation, *Elaters* or Spring-beetles make their appearance upon trees and fences, and some are found on flowers. They creep slowly, and generally fall to the ground on being touched. They fly both by day and night. Their food, in the beetle state, appears to be chiefly derived from flowers; but some devour the tender leaves of plants.

ELECTRICAL EEL. [See GYMNOTUS.]

ELK, or MOOSE DEER. (*Cervus alces*.) Of all the animals belonging to the genus *Cervus*, none are so large as the Elk, which in size is scarcely inferior to a horse, and its immense horns sometimes weigh near fifty pounds. It is common to both continents, inhabiting only the coldest regions, and is observed to attain larger dimensions in Asia and America than in Europe. It cannot boast of the elegant shape so general in the

the ridge of the neck than in other parts, forming a kind of stiffish mane; under the throat is an excrescence, from which issues a tuft of long hair: the body, which is short and thick, is mounted on tall legs, giving a very ungainly aspect to the animal, which is not diminished when it is in motion, as its gait is a sort of shambling trot.

In Europe the Elk is found chiefly in Sweden, Norway, and some parts of Russia. In Asia it occurs in the woody tracts of the Russian dominions, and in Siberia in particular it is found of a gigantic size. In America it has been found as far north as the country has been explored; its southern range, at former periods, extended to the shores of the great lakes, and throughout the New England states. At present, however, they are seldom heard of to the south of the state of Maine; but in Nova Scotia, around the Bay of Fundy, and in the Hudson's Bay Company's possessions, they are found in considerable numbers. The Elk is a mild and harmless animal, choosing its residence in the midst of forests, and principally supporting itself by browsing the boughs of trees: they feed principally by night; and whenever they graze (which, on account of their short neck and long legs, they do with difficulty), they are observed to choose an ascending ground, for the greater convenience of reaching the surface with their lips.

Though naturally of a peaceable and inoffensive disposition, the Elk displays a high degree of courage, and even ferocity, when suddenly attacked; defending himself with great vigour, not only with his horns, but also by striking violently with his fore-feet, in the use of which he is particularly dextrous. The chase of the Elk or Moose forms an important occupation among the natives of North America, and is performed in different ways, some of which are as remarkable for artfulness as others are for boldness and dexterity: they are also often killed with the gun. Their flesh is more relished by the Indians, and persons resident in the fur countries, than that of any other animal. It bears a greater resemblance, in its flavour, to beef than to venison. It is said that the external fat is soft, like that of a breast of mutton, and when put into a bladder is as fine as marrow. In this it differs from all other species of deer, of which the external fat is hard. Their skins, when properly dressed, make a soft, thick, pliable leather, which the Indians prepare by scraping them to an equal thickness, and removing the hair: they are then smeared with the brains of the animal, until they feel soft and spongy; and, lastly, they are suspended over a fire made of rotten wood, until they are well impregnated with the smoke.

"The Moose," says Mr. Gosse, the author of the "Canadian Naturalist," "is more shy and difficult to take than any other animal. He is more vigilant, and his senses more acute, than those of the buffalo or caribou, while he is more prudent and crafty than the deer. * * * I know not whether the Moose has ever been tamed; but I think it not improbable that it could be trained to harness as

ELK. (*CERVUS ALCES*.)

rest of the deer tribe; the head being disproportionately large, the neck short and thick, and the horns dilating almost immediately from the base into a broad palmated form; while its long legs, high shoulders, and heavy upper lip, hanging very much over the lower, give it an imposing, although uncouth rather than a majestic appearance. The colour of the Elk is a dark grayish brown, but much paler on the legs and beneath the tail. The hair, which is of a strong, coarse, and elastic nature, is much longer on the top of the shoulders and on

well as its congeners, the reindeer and the wapiti; and it would, from its size and strength, be more serviceable than either of them. But in a new country like this, where alone the opportunity for such an experiment is to be found, the inhabitants generally have little time, and less inclination, for innovations."

Many extraordinary accounts have been circulated by travellers who wrote in the 17th century, of Elks or Moose Deer being seen in North America, whose height was twelve feet, and the weight of whose horns was between three and four hundred pounds. Such stories were probably derived from vague and uncertain descriptions furnished by the Indian tribes. That some animal, however, of the deer kind, far superior in size to any at present known, once existed, is sufficiently proved by the enormous fossil horns which have often been found at a considerable depth in the bogs of Ireland and the Isle of Man, as well as in America and other parts of the world. Their appearance, however, differs so considerably from the horns of the Elk, that it seems now pretty generally agreed among naturalists, that they must have belonged to some species either quite extinct or hitherto undiscovered. They are much longer and narrower in proportion than those of the Elk, and are furnished with brow antlers; and the processes or divisions into which the sides and extremities run are much longer, sharper, and more distant in proportion.

ELEPHANT. (*Elephas*.) Largest of all living quadrupeds, and prodigiously strong, the Elephant is not less remarkable for docility and sagacity. Of this we have concurrent testimony from the earliest ages to the present time; yet, were we to form our ideas of its capacities only from the external appearance of this formidable animal, a sagacious character is the last we should be likely to give it credit for. The whole form is awkward; the head is large, the eyes extremely small, and the ears very large and pendulous: the body is huge and thick, and the back much arched; the legs are very clumsy and shapeless, and the feet slightly

AFRICAN ELEPHANT — (*Elephas africanus*)

divided into five rounded hoofs: but under this uncomely exterior are qualities which entitle its possessor to the admiration of mankind—a mild and gentle disposition,

superior intelligence, great attachment to its master, and invincible perseverance. In point of bulk, the Rhinoceros and the Hippopotamus are the only existing terrestrial animals that can approach the Elephant; though some other species of *Pachydermata* now extinct must have considerably surpassed him. The enormous weight of the body could only be sustained by legs of the most solid construction; and accordingly we find that these have the aspect of straight columns, the joints being so formed that each bone rests vertically upon the one beneath it.

Elephants, of which only two species at present exist, viz. the Asiatic and the African, are distinguished by their extraordinary proboscis or trunk, by the possession of two enormous tusks, which project downwards from the upper jaw, and by the absence of front teeth in the lower. The African and Asiatic species differ from each other in the size of the tusks, which are much longer in the former than in the latter. In the young animals the tusks are not visible; in the more advanced state of growth they are extremely conspicuous; and in a state of maturity they project in some instances six or seven feet; nay, several tusks measured by Eden were nine feet in length; and Hartenfels measured one which exceeded fourteen feet! The largest tusk on record was sold at Amsterdam, and weighed 330 lbs. It is but rarely that the tusks are seen in the females; and when they appear, they are but small, and their direction is rather downwards than upwards. The African Elephant is said to be smaller than the Asiatic; yet the ivory dealers in London affirm that the largest tusks come from Africa, and are of a better texture, and less liable to turn yellow than the Indian ones. The increase of the tusks arises from circular layers of ivory, applied internally, from the core on which they are formed; similar to what happens in the horns of some animals.

But it is the trunk of the Elephant which may justly be considered as one of the miracles of Nature; being, at once, the organ of respiration, as well as the instrument by which the animal supplies itself with food, and sucks up the water it requires to allay its thirst. This wonderful organ is cartilaginous, and composed of numerous rings, divided through its whole length by a septum, and forming a sort of double tube, terminating in a kind of finger-like appendage or movable hook. "Endowed with exquisite sensibility, nearly eight feet in length, and stout in proportion to the massive size of the whole animal, this organ," as is well expressed by Mr. Broderip, "at the volition of the Elephant, will uproot trees or gather grass—raise a piece of artillery or pick up a combat—kill a man or brush off a fly. It conveys the food to the mouth, and pumps up the enormous draughts of water, which by its recurvature are turned into and driven down the capacious throat, or showered over the body. Its length supplies the place of a long neck, which would have been incompatible with the support of the large head and weighty tusks. A glance

at the head of an elephant will show the thickness and strength of the trunk at its insertion; and the massy arched bones of the face and thick muscular neck are admirably adapted for supporting and working this powerful and wonderful instrument."

Elephants are naturally gregarious; large troops assembling together, and living in a kind of society. The skin of the Elephant is of a deep ash-coloured brown; but in some parts of India it is said to be found, though rarely, of a white or cream colour. It sometimes arrives at the height of twelve or fourteen feet, though the more general height seems to be about nine or ten feet. These animals are commonly found in the midst of shady woods, being equally averse to extreme heat as to cold; they delight in cool spots, near rivers, and, as they swim with great ease, they frequently bathe in the water. Their general food consists of the tender branches of various trees, as well as of grains and fruits; on which account it is that their incursions are so much dreaded in plantations of various kinds, where they are said occasionally to commit the most violent depredations; at the same time injuring the crops by trampling the ground with their huge feet.

The wild Elephants of Ceylon, which are much esteemed, live in small groups or families. In wandering from place to place, the males, who are furnished with the largest tusks, put themselves at the head, and are the first to face every danger. In swimming

ASIATIC ELEPHANT.—*Elephas indicus*.

over any large river, they lead the van, and seek a proper landing-place: next follow the young Elephants, clinging to each other by means of their trunks, whilst the remainder of the full-grown bring up the rear. In all ages these animals have been eagerly hunted; and some of the arts which have been employed to kill or take them merit attention. The Hottentots in South Africa shoot them with tin balls: this chase is attended with considerable danger; for, with every precaution that can be used, the sagacity of the Elephant often detects the approach of the hunter, who, in this case, will, in all probability, fall a victim to the rage of the animal, unless he can instantly disengage him. In the Island of Somatra, the inhabitants split sugar-canes (of which food, the Elephant is very fond), and impregnate them with poison. In Abyssinia they are pursued by hunters on horseback, in the

following manner:—Two men, perfectly naked, mount the same horse; the hindermost is armed with a broadsword, the lower part of which is covered with cord, and the remainder is exceedingly sharp. In this manner they pursue the Elephants, and, having singled out one, they irritate him to attack them, when they ride up close to him, and the armed man slips from the horse on the off side, and, whilst the Elephant's attention is engaged with the horse, he divides the tendons of his foot with a single blow, and thus disables him, when he is dispatched by lances.

They are also taken alive in pitfalls, or are driven into enclosures; in either case they are fed gently, though regularly, for a few days, when tame Elephants are employed to engage their attention till they can be tied fast to a tree; after they have become somewhat dispirited, they are led away between two tame ones, and put under the care of keepers, who gradually bring them into subjection,—more, however, by caresses and soothing, than by coercion. When tamed, they become the most gentle and obedient of all domestic animals, and, in most cases, are exceedingly fond of their keepers, and soon learn to distinguish the various tones of the human voice, as expressive of anger, approbation, or command. The domesticated Elephant performs more work than six horses, but at the same time requires much care, and a plentiful supply of food. He is generally fed with rice, either raw or boiled, and mixed with water. To keep him in full vigour, a hundred pounds of this food is said to be required daily, besides fresh herbage to cool him; and he must be led to the water twice or three a day to bathe. His daily consumption of water as drink is about forty gallons.

It would be difficult to enumerate all the services of these useful animals, so varied are they, and so valuable where strength is necessary. They are employed in carrying burdens on their bodies, necks, and even in their mouths, by means of a rope, the end of which they hold fast with their teeth; they load a boat with amazing dexterity, carefully keeping all the articles dry, and disposing them where they ought to be placed. In propelling wheel carriages heavily laden upon a declivity, they push them forward with their forehead, and support them with their knees. In dragging beams of wood along the ground, they remove obstacles or elevate the ends of the beams so as to clear them. Before the invention of fire-arms, they were used in war by many nations of antiquity; and they are still employed in the East in dragging artillery over mountains. In many parts of India, Elephants are made the executioners of justice; for they will with their trunks either break the limbs of a criminal, trample him to death, or pierce him with their tusks, as they may be directed. The Elephant has been long made the companion of the sports of the Orientalist in the great hunting parties; and from the same early period has been made to minister to the wanton and cruel pleasures of Eastern princes, by being stimu-

lated to combat not only with other Elephants, but with various wild animals: in short, were it consistent with the limits of this work, we might fill many pages with matter, both historical and anecdotal, relating to the uses of this noble animal. We may, however, observe that, its strength being equal to its bulk, it is able to carry on its back three or four thousand weight; on its tusks alone it can support near one thousand; and its ordinary pace is equal to that of the horse at an easy trot.

In the preceding part of this article we have dwelt particularly on the Elephant's trunk and tusks, as deserving especial notice: the organ of hearing would scarcely appear to deserve less. The structure of the Elephant's ear has been investigated with great accuracy by Sir Everard Home. The drum, and every other part of the organ, is much larger in proportion than in other quadrupeds, or in man; and there is a remarkable difference in the arrangement of the muscular fibres of the drum of its ear, when compared with some quadrupeds and the human species. In the human ear, those fibres are radia of a circle; and in the horse, the hare, and the cat, they are of an uniform length; but in the Elephant's ear these fibres are so placed that some are more than double the length of others. Sir E. Home argues, from this remarkable construction, that the Elephant has not a musical ear; but that it has a peculiar compensating power in this length of fibre, as its slower vibrations enable it to hear sounds at a great distance.

The tusks of the Elephant have long been applied, under the denomination of *ivory*, to a variety of important uses in the arts. From the fossil remains which have been discovered, it is apparent that they must have been abundantly distributed over the earth; and some of them appear to have been adapted to a much more northern climate than is now inhabited by the Elephant. It is, indeed, a most curious fact, that skeletons nearly allied to, if not quite resembling, those of Elephants are occasionally found in a fossil state, and in large quantities, at a great depth under the surface, in Russia and Siberia. "All the arctic circle," says Pennant, "is a vast mossy flat, formed of a bed of mud or sand, apparently the effect of the sea, and which gives reason to think that that immense tract was in some distant age won from it. With them are mixed an infinitely greater number of marine bodies than are found in the higher parts of that portion of Asia. I give the fact: let others, more favoured, explain the cause how these animals were transported from their torrid seats to the Arctic regions: I should have recourse to the only one we have authority for; and think that phenomenon sufficient. I mention this, because modern philosophers look out for a later cause: I rest convinced, therefore, to avoid contradicting what can never be proved." Dr. Falconer and Major Cantley have brought from the Sewalik Hills in India numerous fossil remains of Elephants, some of them of enormous size. They are all in the truly magnificent collec-

tion of the British Museum, and are described by the donors in their well-known work, the *Fauna Antiqua Sivalensis*; the illustrations of which by Mr. Ford will hereafter be cited, like the work of Lyonet (alluded to under *Cosses*), as a perfect example of excellence in the drawing of *Fossils*.

ELMIS: ELMIDÆ. A genus and subfamily of aquatic Coleoptera, small in size and of an ovate form, found adhering on the under sides of stones lying at the bottom of running water. They are unable to swim, but are provided with very powerful tarsi and ungues, by which they are enabled to retain firm hold on the stones in the most boisterous currents. Twelve or thirteen species belonging to three genera have been found in this country.

ELOPS. (*Elops saurus.*) A small fish, known in the West Indies by the name of the *Seiu-fish*, or *Sea Gally-Wasp*. It is about fifteen inches long; in the middle five inches round, and tapering to both ends; the head is smooth, and without scales; the tail much forked, and armed both above and below by a strong spine, forming a first or spiny ray on each side the tail. Its general colour is a silvery gray; dusky on the back, the head slightly tinged with yellow, the fins of a bluish brown, and the belly white.

EMARGINULA. A genus of small Mollusca, inhabiting the seas of all climates, and having two short tentacula, with eyes at the base; foot large and thick. The shell is patelliform, oblong, or oval; anterior margin notched. The *Emarginula* may be known from *Patella* and other approximating genera, by the notch or slit in the anterior edge. Recent species, though widely diffused, yet not numerous; fossil species, rare.

EMBERIZA. The name of a genus of Passerine birds. [See *BUNTING*.]

EMBLEMA PICTA, or PAINTED FINCH. This Passerine bird is a native of the north-west coast of Australia. It is described and figured by Mr. Gould; and exhibits a singularity in colouring which is rarely ever witnessed among the feathered tribes, the upper parts of the plumage being remarkably plain, while the under surface is extremely beautiful. The face and throat are deep vermillion-red; crown of the head, all the upper surface, and wings, brown; the base of all the feathers of the throat black, giving to that part a mingled appearance of black and red; rump deep vermillion-red; tail dark brown; chest and all the under surface jet-black; the flanks thickly spotted with white; and the centre of the abdomen deep vermillion-red; upper mandible black, under mandible scarlet; feet light red.

EMERALD [MOTHS.] A name given by collectors to Moths of the genus *Hipparchus*.

EMPEROR [MOTH]. The name of a species of Saturnia; a genus of nocturnal Lepidoptera. [See *SATURNIA*.]

EMU, or EMEU. (*Dromais Novæ Hollandiæ*.) This singular bird is a native of Australia, and allied to the Cassowary; nearly equalling the Ostrich in bulk; but has shorter legs, a shorter neck, and is thicker in the body. Dr. Latham says, This bird measures more than seven feet in length; the beak is black; the plumage for the most part brown and gray mixed, paler on the under parts: the head differs greatly from that of the common Cassowary, being covered with feathers; nor has it any helmet or rising protuberance whatever, as in that

EMU.—(*DROMAIS NOVÆ HOLLANDIÆ*)

species; the feathers, however, about the head and neck are of a hairy texture, and the fore part of the chin and throat nearly destitute of any, so that the purple colour of the skin may be seen through them: the long feathers observable in the wings of the Cassowary of the Old Continent are here wanting; but instead of them are real wings, though of so small a size as to be useless for flight; they are covered with feathers like the rest of the body, and when the bird is quite at rest, are scarcely discernible therefrom. The legs are stout, similar to those of the Galeated Cassowary, but greatly indented or jagged at the back part: the three toes placed in the same manner, all forwards. So far the external appearance of the bird: internally it is said to differ from every other species, particularly in having no gizzard, and the liver being so small as not to exceed that of a blackbird. It is shy and timid, trusting to its great speed for safety, except when hard pressed; it then strikes violently with its legs. The flesh of the young is delicate, but that of the full-grown bird is coarse; it is pursued, however, for the oil that is obtained from it, of which the skin produces six or seven quarts.

It is stated by Capt. Grey (*Travels in Australia*), that "Emus are killed in precisely the same manner as Kangaroos, but as they are more prized by the natives, a greater degree of excitement prevails when an Emu is slain; shout succeeds shout, and the distant natives take up the cry until it is sometimes re-echoed for miles: yet the feast which follows the death is a very exclusive one; the flesh is by far too delicious to be made a common article of food,—hence, heavy penalties are pronounced against young men, and unauthorized persons, who venture to

touch it; and these are invariably rigidly enforced."

At a meeting of the Zoological Society of London (Feb. 23. 1847), the Earl of Derby observed that it was generally supposed that these birds, like most of the *Rasores*, are polygamous: this, however, was not the fact: the Emu is strictly monogamous; and the male, who attends to the eggs, by no means approves of any other female than the favoured one coming near the nest.

EMU-WREN. The name given in Australia to a singular small species of *Malurus*, the *Stipiturus malachurus*; so called from the tail feathers being loose webbed and bearing some resemblance to the double feathers of the Emu.

EMYDÆ. A family of Testudinous animals, known as MARSH TORTOISES. They inhabit warm climates both of the Old and New World, and are found also in Australia, where hitherto no land Tortoise has been detected. Their shell is more convex than that of the latter; their feet are webbed, and their toes are armed with sharp claws. Though they seldom venture far from the water, which is their natural element, and which they invariably seek as a refuge from

MARSH TORTOISE.—(*EMYDÆ FLOTA*)

danger, they are far more active and alert on land than those species which are well-known to us as Land Tortoises. They are carnivorous in their habits; eagerly pursuing frogs, fishes, newts, and insects; and some of them are really formidable from their size and ferocity. [See TORTOISE.]

We refer our readers to the great work of Professor Bell, and to Mr. Gray's very admirable Catalogue of the Tortoises in the British Museum, where all the species are described.

ENALIOSAURI. The name applied to that order of Reptiles which contains the fossil genera *Ichthyosaurus* and *Plesiosaurus* [which see].

ENCHELIDES. A genus of animalcules, the forms of which are extremely various. In some, scarcely any definite shape can be discovered; their bodies appearing to be composed of a mass of gelatinous matter without any solid support.

ENCRINITES. A genus of petrified radiated animals commonly called *Stone Lilies*. Speaking of their rare occurrence in our modern seas, and of their vast numerical importance among the earliest inhabitants of the ancient deep, Dr. Buckland observes:—"We may judge of the degree to which the individuals of these species multiplied among the first inhabitants of the sea, from the

countless myriads of their petrified remains which fill so many limestone-beds of the transition formations, and compose vast strata of entrochal marble, extending over large tracts of country in Northern Europe and North America. The substance of this marble is often almost as entirely made up of the petrified bones of *Encrinurites* as a corn-rick is composed of straws. Man applies it to construct his palace and adorn his sepulchre; but there are few who know, and fewer still who duly appreciate, the surprising fact, that much of this marble is composed of the skeletons of millions of organized beings, once endowed with life, and susceptible of enjoyment, which, after performing the part that was for a while assigned to them in living nature, have contributed their remains

LILY ENCRINURITE — (*ENCRIURUS LILIIFORMIS*.)

towards the composition of the mountain masses of the earth. Of more than thirty species of Crinoids that prevailed to such enormous extent in the transition period, nearly all became extinct before the deposition of the lias, and only one presents the angular column of the Pentacrinite: with this one exception, pentagonal columns first began to abound among the Crinoids at the commencement of the lias, and have from thence extended onwards into our present seas. Their several species and even genera are also limited in their extent: e. g. the great Lily Encrinurite (*E. moniliformis*) is peculiar to the muschel-kalk, and the Pear Encrinurite to the middle region of the oolitic formation.

ENHYDRA. The generic name of the Sea Otter of California (*Mustela lutris*, Lin.) See OTTER.]

ENTOMOPHAGA. The name given to a group of Hymenopterous insects, whose larvæ generally feed, parasitically, upon living insects.

ENTOMOSTRACA. A division of the class *Crustacea*, comprising those animals which have only a slight integument in the form of a shell to protect them; of which the genus *Cypris* (many species of which occur in this country) may be given as an example. Their exceeding minuteness and extreme delicacy of structure have deterred most naturalists from examining them and studying them as they require to be studied—fresh from their native habitats. The difficulty of preserving them obliges the naturalist to seek them in their secret lurking places—the fresh-water ponds and ditches,

and the little pools in the rocks on the seashore, where they are chiefly to be found, and to study them as it were on the spot, with the aid of his microscope. Dr. W. Baird, who has some ingenious remarks on Entomostrea in "The Zoologist" (after alluding to what Latreille had said respecting their organs of mastication being too minute for human observation), says, "The organs of mastication are not however the only organs that are worthy of being noticed. The beautiful and delicate structure of their feet and branchial appendages are worthy of all admiration. These latter organs are almost constantly in motion, and present a most interesting appearance when viewed under the microscope. The extraordinary method they have of reproducing their young, with the transformations which some of them undergo in an early stage, are subjects which might occupy a considerable time in describing, and which cannot be attended to without exciting the greatest interest in the mind of the observer." Dr. Baird has monographed all the British species, and published also descriptions of several exotic species. [See CYPRIS.]

ENTOMYZA. A genus of birds belonging to the *Meliphagidae*, of which we may mention one of the best known species.

ENTOMYZA CYANOTIS, called by the colonists of New South Wales BLUE-EYE. This bird is found almost exclusively on the Eucalypti, searching among the blossoms and smaller leafy branches for its food, which consists partly of insects and partly of honey, and, as others of the group do, probably, on berries and fruit. They are bold and spirited birds, pugnaciously chasing and drawing about the other species resorting to the same tree. Its cry is loud and monotonous. In every instance that Mr. Gould found its eggs, they were deposited on the deserted, dome-shaped, large nest of the *Pomatorhinus*, never within the dome, but in a neat round depression on the top. It commences breeding early, and has at least two broods in a year.

ENTOZOA. A name given to an extensive series of low-organized invertebrate animals, the majority of which are inhabitants of the bodies of other animals during greater part of their existence. They live upon nutriment derived from the tissue or organs in which they dwell; they have colourless blood, no respiratory organs, properly so called, and no articulated members of locomotion. The individual or animal whose body they infest, or who, in other words, entertain their presence, is technically denominated the *host*. (For further particulars of this interesting group, see articles *INTESTINALIA*, p. 36; *FILARIA*, p. 230; *FASCIOLE*, p. 228; *TENIA*, p. 661; and also *GENUS* and *ALTERNATION OF GENERATION* in SUPPLEMENT.)

ENTOZOON. A crustaceous parasite, found in the sebaceous follicles of the human skin. It is the *Demodex folliculorum* of Owen.

EPHEMERA; EPHEMERIDÆ. A genus

and family of Neuropterous insects, characterized by the unequal size of the wings; the minute size of the antennae; the membranous and almost obsolete mouth; and the elongated articulated setae at the extremity of the body, which is long, soft, and slender: the eyes are large, nearly oval, and three ocelli are placed triangularly between them. The most familiar species is the *Ephemera vulgata*, or common MAY-FLY, so plentiful in the early part of summer about the banks of our rivulets and stagnant waters. It is of a greenish brown colour, with transparent wings, elegantly mottled with brown, and is furnished at the extremity of the body with three very long black bristles. It flutters in the evening about the surface of the water, but during the day is generally seen in a quiescent posture, with the wings closed, and in an upright position. The larva is about an inch in length, having several finny plumes on each side the body, and at the tail three long feathered processes: it has also a pair of moderately long antennae, though those of the complete insect are extremely short. When arrived at its full size, as above described, it exhibits the rudiments of wings on the back, in the form of a pair of oblong sheaths or scales; its colour being a yellowish or whitish brown. It is supposed to continue in this kind of larva state two years before it assumes the condition of the complete insect. This change takes place in the evening, when the larva rises to the surface of the water, and soon divesting itself of its skin, flies to some neighbouring object, and after having remained some time longer, again casts its pellicle, and appears in its ultimate or perfect form, in which, as well as in its larva state, it is a favourite food of several kinds of fishes, particularly of the Trout. In some seasons it is extremely plentiful, the air in the immediate vicinity of its natal waters being frequently blackened by its numbers during the evening hours.

Swammerdam, the well known writer on Insects, observes, that notwithstanding the dangers to which the eggs, larvae, and pupae are constantly exposed, from the attacks of fishes and predaceous aquatic insects, the number of specimens which arrive at the perfect state is sometimes so immense, that the swarms of one species with white wings (*Ephemera albigenuis*) has been compared to a fall of snow; whilst, in some parts of Europe where they abound, it is the custom to collect their dead bodies into heaps, and use them for manure. The fishes at such time eagerly wait for them; and so great are the numbers which fall into the water, that the fishermen call them manna.

But the most celebrated of all the Ephemeræ is the species popularly termed the DAY-FLY. It is of a white colour, with the anterior rib of the upper wings black or deep brown, and the tail is furnished with two long bristles. This insect is commemorated as a most remarkable instance of the brevity of animal life; since after its change into the perfect fly it survives but a very few hours, perishing in the course of the same evening that gave it birth. It is to be recollected, how-

ever, that its larva lives in its aquatic state two, and even sometimes nearly three years; but when arrived at the proper period, it rises in the evening to the surface of the water; and the skin of the back cracking, and flying off with an elastic motion, the Fly is almost instantly evolved, as in the common species; after which it flies to the nearest convenient spot, and again divesting itself of its pellicle, appears in its last and perfect state. It now flies again to the water, and flutters over its surface, as if sporting with its innumerable companions, enjoys all the pleasures of its short remainder of existence: the female breeds, deposits her eggs, and, like the male, perishes before or with the dawn of the approaching day. There are several other species of Ephemeræ.

EPIORNIS. [See SUPPLEMENT.]

EPIMACHUS. A genus of birds allied to the Hoopoe, having, like them, a slender beak, but with velvety or scale-like feathers partly covering the nostrils, as in the Birds of Paradise. The plumage in the species figured is of the most gorgeous description. It is of a deep black, with the feathers magnificently glossed with various colours; the

EPIMACHUS MAGNIFICUS

long plumes on the flanks being elongated, turned up, and frizzled: the edges of a burnished steel blue, sometimes inclining to green. It is a native of some of the islands in the Eastern seas, and, like the Birds of Paradise, to which some naturalists have thought it allied, would form a truly beautiful ornament to our aviaries and zoological gardens.

EPOMOPHORUS. A name applied by Mr. Bennett to one or two species of Foxbats (*Pteropidae*) from W. Africa, which have remarkable tufts of hairs on the sides.

EQUUS. The generic name of certain quadrupeds with solid or undivided hoofs; as the Horse, the Ass, and the Zebra. "This family," says Mr. Gray, speaking of the *Equidae*, (which is distinguished from all other animals by its undivided hoof, formed of the two anterior toes soldered together, its simple stomach, and its female having the teat placed on the pubes) "may be divided

into two very distinct types of form: the one, the Asses and the Zebras, which are always whitish and more or less banded with blackish-brown, and always have a distinct dorsal line, the tail only bristly at the end, and have warts only on the arms and none on the hind legs; and the true Horses, which are not banded, have no dorsal line, are furnished with warts on their arms and legs, and have long hair on the tail, from its insertion to its extremity." Of these species the Horse is by far the most valuable, as well as the most widely distributed over the globe. Dental character of this genus:—six incisors in the front of both the upper and lower jaws, one canine or tusk, and six molars or grinders, on each side of both jaws; in all forty. [See HORSE.]

ERINACEUS. [See HEDGEHOG.]

EBIOMYS. [See CHINCHILLA.]

ERIPHIA. A genus of Decapod short-tailed Crustacea, of which there are several species; one of which, *E. spinifrons*, is com-

GOUTY ERIPHIA.—(ERIPHIA GONAGRA.)

mon in the Mediterranean. The *E. gonagra* is a fine species, with tuberculated fore-legs, found in Brazil. In the Indian Ocean other species are found.

ERMINE. (*Mustela erminea*.) This little digitigrade animal, which is also called the Stoat, resembles in its general appearance the Weasel, but is considerably larger, the Ermine measuring ten inches in length, independent of the tail, whereas the Weasel seldom exceeds six. The colour of the Stoat is a reddish-brown above, white beneath, the tip of the tail being constantly black, whatever may be the cast of colour on the body; for the Stoat, in the northern regions, becomes milk-white during the winter, in which state it is known as the Ermine: we may therefore properly say, that an Ermine is a Stoat in its winter dress. Like the Weasel, it lives in hollows under the roots of trees; in banks near rivulets; and it preys on birds, poultry, rats, and all kinds of smaller animals, as well as on rabbits, leverets, &c.; it is also a great devourer of eggs. It is an inhabitant both of the northern parts of Europe and of Asia; and is also found in many parts of North America. Like many other species of this genus, the Ermine has the faculty of ejecting a fluid of a strong musky odour. Its fur is short, soft, and silky; its pure white winter coat being much longer, thicker, and finer than that of summer. The fur of the

Ermine is in great request; it was formerly one of the insignia of royalty, and is still used by the judges. When used as linings of cloaks, &c., the black tuff from the tail is sewed to the skin at regular distances.

In the neighbourhood of Hudson's Bay, Ermine are very abundant, particularly in the barren grounds and open plains. In Norway and Siberia also their skins are a great article of commerce. During the winter it is extremely difficult to distinguish them, from their colour so closely resembling that of the snow; and they are generally either taken in traps, or shot with blunt arrows. This animal, which in the pursuit of its prey is one of the boldest of its size, is not readily tamed; but when caught, and kept in a cage, it still exhibits every mark of its ferocious and savage character, by killing or injuring every thing within its reach.

ERNE. A local name for the Sea Eagle, (*Haliaeetus albicilla*) which frequents the seashores. It is distinguished from the true Eagles, by the absence of feathers at the lower part of the tarsi. [See EAGLES.]

ERODY. The name given to a gallatorial bird (*Dromas ardeola*) allied to the Trumpeter, and found both in India and Abyssinia. It is swift of foot, and was found by Mr. Salt in Abyssinia during Lord Valentia's travels.

EROTYLUS: EROTYLIDÆ. A genus and family of Tetramerous Coleoptera, abounding in South America, where they feed generally on fungi. They form the subject of an admirable monograph by M. Lacordaire, who has published a thick

VIOLET-COLOURED EROTYLUS
(EROTYLUS VIOLEACEUS.)

volume on the numerous species. A few small British species belonging to the genera *Triplax* and *Tritoma* are found in this country. Most of the South American species have the maxillary palpi terminating in a large crescent-shaped joint; the antennæ end in a very distinct and perforated mass.

ERYCINA. A genus of Conchifera, or Bivalves, found in the sand on the shores of New Holland and the Mediterranean. Shell ovate or triangular, transverse, equi-valve, smooth; hinge with a ligamentary pit, two diverging cardinal and two lateral teeth in each valve. There are several fossil, and two recent species. Also the name of a genus of Diurnal Lepidoptera.

ERYCINIDÆ. A family of Lepidopterous insects, distinguished by the fore legs of the males being only rudimental: the anal edge of the hind wings is but slightly prominent, and the discoidal cell is either open or closed, partially or entirely, by a false nervure. The caterpillars are very short, pubescent, or hairy; and the chrysalis is short and contracted. These insects are of small size, and generally of very brilliant colours, often varied, and their wings marked with spots. They are almost exclusively confined to South America. Their flight is very rapid, and the majority of them rest with their wings extended on the under side of leaves. Some of the species have the hind wings produced into two or more tails, often of very great length; in this particular resembling the genera *Papilio* and *Thecla*; others bear a certain resemblance to the *Hipparchia*, *Heliconia*, &c. See the fine work of Messrs. Doubleday and Hewitson for the numerous genera and species of this family, where all the leading forms are beautifully figured. In the British Museum there is a very large collection of them.

ESOX: ESOCIDÆ. A genus and family of voracious fishes, many of them inhabitants of rivers. They are destitute of the adipose fin, and the border of their upper jaw is either formed solely by the intermaxillaries, or they have no teeth. The different sub-genera vary greatly in the form of the body, the size of the scales, the length of the jaws, and other striking points. [See *FISH.*]

ESQUIMAUX DOG. [See *DOG.*]

ETHERIA. A genus of *Cochifera*, or *Bivalves*, found in the rivers of Africa and Madagascar. Shell inequivalve, very irregular; teeth none; hinges short and indistinct; ligament external, penetrating partly into the shell. In its foliated structure and toothless hinge it resembles *Ostræa*, but differs from it in having two muscular impressions. The exterior is rugged and irregularly shaped, but the interior of the valves is pearly, of a vivid green colour, and raised in small blisters, which are said to be formed by small particles of sand being accidentally introduced during the formation of the nacreous fluid. These shells are abundant in the Nile above the cataracts, where the inhabitants collect them for the purposes of ornamenting their tombs with them. In Lake Tchad, in Central Africa, Major Denham found a fine species of this genus.

EUCHIRUS: EUCHIRIDÆ, or LONG-HANDEN BEETLE. A remarkable genus and family of *Lamellicorn* beetles; the longest known species of which is represented in the two accompanying figures; one of which is the male, and the other the female. The species (*E. longimanus*) is found in the East Indies, where it seems to be by no means common. It is of a rich reddish-brown colour. The two cuts will show the form of the sexes of this species better than the most elaborate description. The insect is most probably a native of one of the islands in the East Indian Archipelago. Another

LONG-HANDED BEETLE: MALE
(*EUCHIRUS LONGIMANUS*.)

species (*E. quadrilineatus*) in the British Museum collection, was found by Mr. Cumming in the Philippine Islands. It is distinguished, among other marks, by four lon-

LONG-HANDED BEETLE: FEMALE.
(*EUCHIRUS LONGIMANUS*.)

gitudinal lines on the clytra. A third most gorgeous species, has been named by Mr. Hope *Chirotonus Macleani*. It is of the most brilliant metallic green; the clytra being black, with variously shaped orange spots. A closely allied species to this, also in the

British Museum, and described by Mr. Gray, is the *Ch. Parrit*. Another insect belonging to this group is the *Propomacrus arbaces*, from Smyrna, described by Pullas, and figured by Mr. Newman in the Entomological Magazine. Little, if any thing, is known of the habits of this remarkable group of Lamellicorn beetles.

EUDYNAMIS. A genus of Cuckoos, found in Asia and the Eastern Islands. The best known species is the *Eudynamis orientalis*. [See Cuckoo.]

EUMENIDÆ. A family of Hymenopterous insect, of predaceous habits. Reaumur has given the history of a species of this family (*Odynerus*). "This insect," says Mr. Westwood, in his useful compilation, the 'Introduction to the Modern Classification of Insects,' "during the early months of summer, forms a burrow in the sand to the depth of several inches, in which it constructs its cells; besides which it builds, with the grains of sand brought up whilst burrowing, a tubular entrance to the burrow, often more than an inch long, and more or less curved, the grains of sand of which it is formed being agglutinated together; each female forms several of these burrows, and deposits an egg in each cell, together with a number of green caterpillars, which it arranges in a spiral direction, one being applied against the other, and which serve as food for the larve when hatched. When the store of food is secured, the insect closes the mouth of the burrow, employing the grains of sand of which the funnel was composed for that purpose. The larve of *Odynerus* are fleshy grubs, destitute of feet, with transverse dorsal tubercles serving in their stead. * * * Geoffroy has described a species of *Eumenes* which differs somewhat in its habits from the rest of this family. This species constructs, upon the stems of plants, especially heath, small spherical nests, formed of fine earth: at first a hole is left at the top, through which the parent fills the cell with honey, and deposits a single egg therein; the hole is then closed up, and the larva, when hatched, feeds on the honey, undergoes its metamorphosis, and makes its escape through a hole which it forms at the side of the cell, which contains but a single insect."

EUPHEMA. A genus of the *Psittaculæ* or parrot tribe; several species of which are found in Australia. The bill is almost always very much concealed by the long feathers about the face. In Mr. Gould's national work, "The Birds of Australia," several species are described and elegantly figured: of these we may specify—

EUPHEMA AURANTIA, or ORANGE-BELLIED GRASS PARAKEET. This species is not very abundant in Van Diemen's Land, but in Aetcon Islands, in D'Entrecasteau Channel, it is the only bird enlivening the solitary place.

EUPHEMA CHRYSOSTOMA, or BLUE-BANDED PARAKEET. This beautiful bird is a summer resident of Van Diemen's Land, arriving there in September, and leaving in Febru-

ary and March; running over the ground, and treading its way among the grasses, to feed on the seeds. Its flight is very quick. It can easily be domesticated, and a more elegant or beautiful pet can scarcely be conceived.

EUPHEMA ELEGANS, or ELEGANT GRASS PARAKEET. This species inhabits South Australia, and is the "Ground Parakeet" of the colonists. It feeds on grass seeds;

ELEGANT GRASS PARAKEET
(EUPHEMA ELEGANS)

congregating in the hot seasons (where there is water in small pools) in almost incredible numbers. Its flight is rapid and even, and frequently at great altitudes. For our figure of this elegant bird we are indebted to the work of Mr. Gould.

EUPHEMA SPLENDIDA, or SPLENDID GRASS PARAKEET, inhabits the neighbourhood of the Swan River, in Australia. [See MELOPSITTACUS.]

EUPHONIA. A genus of birds allied to the *TAXANERÆ*, of which there are many species. We restrict ourselves in this article to the *EUPHONIA JAMAICA*. This is a small Passerine bird, known in the West Indies as the "Blue Quilt," and sometimes also called the Blue Sparrow. It is about four inches and a half long, and rather of an inelegant shape from the abrupt shortness of its tail. The upper parts of the male are of a glossy blue, sometimes tinged with green; throat, breast, and sides pale gray; belly yellow; beak gray, the ridge and tip black. It is common about homesteads, frequenting fruit-trees, busily hopping about the twigs and fruits and picking in any position. It is by no means destitute of musical powers, sometimes delighting in a soft warbling repetition of a single note, and at others treating its hearers with a real song, sweet and musical. Mr. Hill, a gentleman of Jamaica, whose ornithological notes contribute to the entertaining character of Mr. Gosse's work, gives the following description of this little active warbler. "Near the piazza of my house a cotton-bush has flung out its knots of white filaments. Hither come the birds at this season (February) to gather materials for constructing their nests. The Blue Sparrow, a pretty little frugivorous bird that sings in our fruit trees, all the year round, its merry twittering song, has been busily

engaged with his mate collecting bill-fuls of cotton. It did not seem to be a thing immediately settled that they should set to work and gather their materials at once. They had alighted on the tree as if they had very unexpectedly found what they were seeking. The male began to twitter a song of joy, dancing and jumping about; and the female, intermingling every now and then a chirp, frisked from stem to stem, and did very little more than survey the riches of the tree: at last she plucked now and then a bill-full of the filaments, and spreading it to flout to the wind, tossed it away, as if she had been merely showing that it every way answered the purpose of length and softness, and was in every respect the thing they wanted." We are also told that they build a very snug domed nest, globular in form, and about as large as an infant's head, with an opening in one side, composed of dry grass, the dried stems of the *Tillandsia*, tendrils of passion-flower, bits of rag, &c., profusely intermixed with cotton and the down of plants.

EUPLECTELLA. [See SUPPLEMENT.]

EUPLOCOMUS. An Asiatic genus of Pheasants, of which the males have usually very brilliant plumage. [See PHEASANT.]

EURYALE. A remarkable genus of Radiated animals belonging to the *Asteriadae*, or Star-fishes, in which each division of the rays is branched again and again, so

WARTED EURYALE.
(EURYALE VERRUCOSUM.)

that the whole resembles a bunch of serpents' tails. The figure which we subjoin represents the whole of the body, with only two of the rays given in detail, as the cut would otherwise occupy too much space. They are sometimes known by the name of Medusa's heads. These little branches must

be of singular use to the animal in securing its prey. In the cases of *Radiata* at the British Museum may be seen some fine examples of these "tufts of the deep." [See STAR-FISHES.]

EURYNOME. A genus of Crustacea, belonging to the family *Lambridae*; of which one species is found in the British seas—the *Eurynome aspera*. It is a pretty little species, rough with projecting knobs; often symmetrically arranged, and of a reddish colour. The fore legs in the male are elongated.

EVANIADÆ. A family of Hymenopterous insects, of small extent, and not possessing any remarkable points of interest. The species are parasitical, the *Irania apantligaster* being attached to the Cockroach (*Blatta orientalis*).

EXOCETUS. [See FLYING-FISH.]

EWE. The female of the Sheep kind. [See SHEEP.]

FAIRY SHRIMP. [See APPENDIX.]

FALCONIDÆ. The genus *Falco* of authors may be considered as constituting five tribes or families of Accipitrine birds, viz. Eagles, Falcons, Kites, Buzzards, and Hawks. They prey, in general, on living animals: the species are extremely numerous; the females are larger than the males; and they vary considerably in their plumage according to age and other circumstances. They are characterized by a powerful beak, which is generally armed with a kind of tooth or process on each side near the apex; and their wings are strong, long, and pointed: they are likewise distinguished by their courage and activity. The true Falcons are symmetrical in their forms; their flight is graceful and vigorous; they possess strength and flexibility; and their sight is so very acute, that they are enabled to discern their prey at a great distance, and to pounce down upon it. The Falcon builds in the hollows of rocks exposed to the south; usually laying its eggs about the close of winter, or very early in the spring: these are often four in number, and are white, spotted with brown. So rapid is said to be the growth of the young, that in the space of three months they equal the parents in size.

The "noble" breed of Falcons which our ancestors introduced into their service, and so greatly prized, are distinguished from the "ignoble" or baser race of kites, sparrow-hawks, and buzzards, by the peculiar length of their wings, which reach almost as far as their tails; this superiority of wing giving them confidence in the pursuit of the game, and their great power emboldening them to attack it. To train these birds, however, required no small degree of skill and assiduity: but so thoroughly antiquated and obsolete has the once princely sport of Falconry become, that we think the reader will commend us for omitting that which a few centuries ago would have been regarded as indispensable: we mean, a circumstantial account of the training, or education, neces-

sary to teach these magnanimous birds the duties of their office. Numberless indeed are the treatises which have been written on the subject, but in language so fraught with professional technicalities, that at the present day they would be almost unintelligible.

THE JERFALCON. (*Falco Gyrfalco.*) This elegant species is generally considered as the boldest and most beautiful of the tribe, approaching in size nearly to that of the Osprey. It is a native of the cold and dreary regions of the north, and is found in Iceland, Russia, Norway, and Baffin's Bay. Its general colour is brown above, in deeper and lighter variegations, and whitish beneath, with brown longitudinal spots; the tail is crossed by numerous deeper and lighter bands, and the bill and legs are generally of a bluish or a pale yellow hue. Buffon mentions three varieties of the Jerfalcon; the first and second very similar to what we have just described; and another which is entirely white. Next to the Eagle, it is the most formidable, active, and intrepid of all rapacious birds, and the most esteemed for falconry. It boldly attacks the largest of the feathered race; and although it is often transported from the coldest regions to some of the warmest, its strength is not diminished by the change of climate, nor its vivacity blunted.

THE PEREGRINE FALCON. (*Falco Peregrinus.*) This species is about eighteen inches in length, and three feet six inches wide when its wings are extended; and in its full growth and plumage is a very fine-looking, strong, and bold bird. The bill is pale blue, tipped with black; short, strong, and much hooked. The general colour on the upper parts is a deep bluish lead-colour, barred with black, but the crown of the head and upper part of the neck nearly black; the greater wing-feathers dusky, barred with oval white spots; and the tail of a dark dingy ash, spotted with brownish black,

PEREGRINE FALCON.—(*FALCO PEREGRINUS.*)

and tipped with pale brown. The under parts, from the chin to the bottom of the breast, are yellowish white, with a deep brown streak down the shaft of each feather; and the remainder are of a dull white, beautifully and distinctly barred with dark brown. The thighs are long, and marked

with small heart-shaped spots; legs short, strong, and yellow; claws black, and the toes long. The Peregrine Falcon appears to be a general inhabitant of Europe and Asia: it is common in the north of Scotland, and is known to breed on the rocks of Llandidno, in Cernarvonshire; which have been long celebrated for producing a "generous race."

THE BLACK-CHEEKED FALCON. (*Falco melanogenys.*) A noble species of the *Falconidae*, noted for its bold and rapacious habits, which is universally dispersed over the whole southern portion of Australia, including Van Diemen's Land. Mr. Gould says it gives preference to steep rocky cliffs, and the sides of precipitous gullies, rather than to fertile and woodland districts. It there dwells in pairs throughout the year, much after the manner of the Peregrine Falcon; its nest being placed in the most precipitous and inaccessible parts of the rocks. Their eggs are two in number, the ground colour buff, thickly blotched with deep reddish chestnut. In alluding to the strength and courage of this bird, Mr. Gould has the following comment: "Thus we find in this Falcon a bird well adapted for the sport of Falconry, which, though fallen into disuse in Europe, may at some future time be revived in this new and rising country, since its lagoons and water-courses are well stocked with herons and cranes, and its vast plains are admirably suited to such pastime. The introduction of hounds for the purpose of chasing the native dog (Dingo) and the Kangaroo has already taken place in Australia; and perhaps it is not too much to look forward to the time when the noble science of Falconry shall be resorted to by the colonists. A finer mews of birds could not be formed in any country than in Australia; with such typical Falcons as *F. hypoleucus*, *F. melanogenys*, and *F. frontatus*."

THE WHITE-BREASTED FALCON. (*Falco hypoleucus.*) This fine bird, which greatly resembles the Jerfalcon, belongs to the Australian fauna, and is interesting, as Mr. Gould remarks, "as adding another species to the true or typical Falcons, and as affording another proof of the beautiful analogies which exist between species of certain groups of the southern and northern hemisphere."

THE GENTIL, OR GENTLE FALCON. (*Falco Gentilis.*) This is described as somewhat larger than a Goshawk, and of an elegant form. The bill is lead colour; the cere and legs are yellow; and the head is of a light ferruginous colour, with oblong black spots. The whole of the under parts are whitish, with brown spots and dashes; the back is brown; the quill-feathers, which are dusky, are barred on their exterior webs with black, and on the lower parts of their inner ones with white: the wings reach to the middle of the tail, which is alternately banded with black and ash-colour, and tipped with white. The legs are yellow and rather short, and the thighs are well covered with feathers.

- There are many other species and varieties; but to give a detailed description of

them all would be more monotonous than interesting.

Among the European nations the French and Germans seem to have been the first to encourage the practice of falconry; and the technical terms used by the English are evidently all borrowed or derived from the French. "In our own country," says Mr. Pennant, "I cannot trace the certainty of falconry till the reign of King Ethelbert the Saxon monarch, in the year 760, when he wrote to Germany for a brace of Falcons which would fly at cranes and bring them to the ground, as there were very few such in Kent. It seems highly probable that falconry had its rise in Scythia, and passed from thence to the northern parts of Europe. Tartary is even at present celebrated for its fine breed of Falcons; and the sport is in such general esteem that, according to Olenarius, there was no hut but what had its Eagle or Falcon. The boundless plains of that country are as finely adapted to the diversion as the wooded or mountainous nature of most part of Europe is ill calculated for that rapid amusement." In England falconry seems to have continued in full glory till about the time of Cromwell, after which it appears to have gradually declined. With what ardour it was pursued in the reign of James I. may be gathered from the anecdote related by Mr. Pennant, who says that Sir James Monson gave no less a sum than a thousand pounds for a cast of Hawks. [See EAGLE, HAWK, &c.]

FALLOW DEER. (*Cervus dama.*) This animal, so graceful an ornament of our parks, in its general form greatly resembles the Stag, having the same elegance of aspect with a more gentle disposition. It is, however, considerably smaller, being only about

FALLOW DEER.-(*CERVUS DAMA.*)

three feet, or rather less, to the top of the shoulder. It is generally of a brownish bay colour, more or less beautifully spotted; and it has a longer tail. The horns of the Fallow Deer are broad and palmated at

their extremities, pointing a little forward, and branched on their hinder sides; they have two sharp and slender brow-antlers, and, above them, two small slender branches; whereas every branch of a Stag's horn is shaped like the stem that supports it: the form of the horns is, in fact, the chief mark of distinction between the two species.

The manners of the Fallow Deer resemble those of the Stag, but it is less delicate in the choice of its food, and browses much closer. It arrives at full growth and perfection in about three years, and is said to live about twenty. The male is called a *buck*. In the first year he is a *faun*; in his second, a *pricket*; in his third, a *sorel*; in his fourth, a *sorc*; in his fifth, a *buck of the first head*; and in his sixth, a *great buck*. The female, or *doe*, in her first year is called a *fawn*; and in her second, a *teg*. The process of acquiring and shedding the horns is in every respect similar to that which takes place in the stag; but the form of them, as we have before described, is very different, and the furrows, &c. are less distinctly marked. Although the males are much less furious in the rutting-season than the Stag, they frequently fight desperately for the possession of the females; and it is not till after repeated conflicts that one buck obtains the sovereignty of the whole. It also often happens that a herd of Fallow-Deer will divide into two parties, and engage each other with great ardour and obstinacy, as if ambitious of securing some favourite spot of pasture, and of driving the vanquished party into the coarser and more sterile parts.

When closely pursued by the hunters, the buck makes towards some strong hold or thicket with which he is acquainted, either in the more shady parts of a wood, or the steep of some mountain; nor does he fly far before the hounds, nor cross and double like the stag: he will take the water, it is true, when hard run; but in strength, cunning, and courage, he is much inferior to the stag, and, consequently, he affords neither so long nor so various a chase. In England there are two kinds of Fallow-Deer: the beautiful dappled kind, supposed to have been brought from the South of Europe, or the Western parts of Asia; and the very deep brown variety, which were brought from Norway by James I., who, while there, noticed that they could endure the cold of that severe climate, and subsist throughout the winter without fodder. Nothing can exceed, in richness and delicacy, the venison of the Fallow Deer. The skins of both the Buck and the Doe are unrivalled for durability and softness; and the horns, like those of the stag, are manufactured into knife handles, &c.; while from the refuse, ammonia (popularly known as *horthorn*) is extracted.

FANFOOT (MOTHS). A name given by collectors to Moths of the genus *Polypogon*.

FANTAIL. (*Rhipidura.*) A genus of Birds belonging to the family *Muscicapidae*, and found in Anstralia. There are more than one species, but we restrict ourselves here to the

RUPIDURA ALBISCAPA, or WHITE-SHAFTED FANTAIL. This bird inhabits Van Diemen's Land and South Australia. It is generally seen in pairs, among trees; while in the air it assumes a number of lively and beautiful positions; at one moment mounting almost perpendicularly, spreading out its tail constantly to the full extent, and frequently tumbling over in the descent. It is a very tame bird, allowing near approach without showing the least timidity, and will even enter houses in the bush in pursuit of gnats and other insects. In the breeding season it is not so familiar. Its nest is

WHITE-SHAFTED FANTAIL.
RUPIDURA ALBISCAPA.

very elegant, resembling a wine-glass in shape; and is generally composed of the inner bark of a Eucalyptus, neatly lined with the down of the tree-fern intermingled with flowering stalks of moss, and outwardly matted together with the webs of spiders, which not only serve to envelope the nest, but also strengthen its attachment to the branch on which it is constructed, which is always within a few feet of the ground. Eggs two in number. Our figure is derived from the beautiful work of Mr. Gould's, and shows the bird flying over its nest.

FASCIOLA, or FLUKE. (*Fasciola [Distoma] hepatica.*) A parasitical animal believed to give rise to that much-dreaded disease called the rot. It is not only found in other ruminants, but likewise infests Man, the Horse, the Hog, and even the Rabbit. In the human subject it is fortunately of rare occurrence. A full-grown example is

usually about three-quarters of an inch in length; its form being leaf-like, with a superior projecting portion (the so-called head), resembling a short stalk, the tail end being gradually narrowed and bluntly pointed. These animals are hermaphroditic, in

FIGURE. — (*FASCIOLA HEPATICA.*)

other words, they are bi-sexual, but, like the Mollusca, they are incapable of fertilising themselves. There are no eyes, or other organs of special sense, although some Entozoologists profess to have discovered a well-marked nervous system. The power of multiplication in these parasites is immense, and the ducts of a single liver have been found to contain upwards of a thousand. From recent investigations and experiments made by Buchenmüller, Leuckart, Siebold, and others, there can be no doubt that these Flukes gain access to the bodies of their creatures they infest whilst they are still in a young condition. The eggs of the parent Fluke having escaped in fields and other open places, the young issue forth from the eggs in the form of ciliated embryos, which swim about in ditches, ponds, &c. After undergoing certain transformations in the water (and probably also in the bodies of aquatic insects, pond-snails, &c.), they are ultimately taken into the bodies of the higher animals along with food or drink. In this way the cycle of their life-development is completed. [See ALTERNATION OF GENERATION in SUPPLEMENT.]

FASCIOLARIA. A genus of Univalves found in the Indian seas, the Antilles, &c., some of which are very beautiful.

FATHER-LASHER. (*Cottus bubalis.*) An Acanthopterygious fish, seldom exceeding eight or ten inches in length, generally found on the rocky coasts of this island, and which is immediately recognized by its large and formidable head, armed with long spines; by

FATHER LASHER. — (*COTTUS BUBALIS.*)

means of which it immediately combats every enemy that attacks it, inflicting its cheeks and

gill-covers to a prodigious size. The mouth, which is large, contains two rows of minute teeth, besides others which are in the roof. The back is much elevated; the belly is prominent; the lateral line is rough, but the rest of the body is very smooth, tapering towards the tail. The colour of the body is a dusky brown, marbled with white, and sometimes stained with red; the fins and tail are transparent; and the belly is a silvery white. It feeds on small crustacea. In Greenland this fish attains a much larger size, and forms the principal food of the natives, who make it into soup, which is said to be both wholesome and palatable.

FAWN. An appellation given to a buck or doe of the first year. [See **DEER**.]

FELIS: FELIDÆ. The name given to animals of the Cat kind, forming a large genus and family of carnivorous quadrupeds, including the lion, tiger, leopard, lynx, domestic cat, &c. They are characterized by having strong, sharp, retractile talons on the feet, and by the teeth being equally fitted for the purpose of destruction. They are all essentially carnivorous; they refuse vegetable food; and in a state of nature they will not, unless pressed by hunger, devour any flesh which they have not themselves killed. They are, consequently, of all Mammalia, the most destructive in their propensities; and their bodily powers are in admirable accordance with their instincts. There are no quadrupeds in which the muscles of the jaws and limbs are more fully developed; their frame is vigorous, but agile; the limbs are well knit, but supple; and every motion is easy, free, and graceful. There is no superfluous flesh; but the whole seems composed of bone, nerve, muscle, and sinew. Though many animals on which they prey excel them in fleetness, in consequence of having longer and more slender limbs, there are none which approach them in the power of leaping and bounding. The under surface of their feet being provided with elastic pads or cushions, their footfall is rendered noiseless; their usual gait is slow, cautious, and stealthy; and when the impetus of the spring is added to the stroke of the paw, their power is almost irresistible. They possess the sense of smell in a very moderate degree, compared with the Canidae; but their sight is most acute, adapted for vision by night as well as by day; the sense of hearing is also exquisite; and the long whiskers are delicate organs of the sense of feeling. The tongue is furnished with rough horny papillæ, directed backwards; these serve a very important purpose in enabling the animal to scrape off the minute particles of flesh adhering to the bones of its prey.

The different species of this family for the most part bear a very close resemblance to one another in general conformation, though differing widely in size; and it is chiefly by their variation in this respect that their habits are guided. In Brande's Dictionary of Science we find the following judicious observations on the distinguishing characteristics of the different species: "The leopards, panthers, jaguars, are the most typical

or truly feline species; in these the beauty of colouring, sleekness of skin, elegance of form, craft, suspicion, bloodthirstiness, agility under excitement, and sloth during repelction, are most strongly manifested. The lion combines more robustness of body with the feline attributes; and his pre-eminent stature receives an air of nobility and grandeur from the mane that decorates his head and neck. He has the credit too of a greater share of boldness and generosity than the other cats. His vocal organs also exhibit a modification of structure not present in the other felines, by which he has the power to utter his tremendous roar—a roar which, when sent forth under the excitement of hunger, scares from their hiding places the timid ruminants which may be lurking within the compass of its fearful reverberations. Among the felines, one group is characterized by the shortness of the tail, and the tuft of hair on the tips of the ears; this includes the lynxes.

"The electah, or hunting leopard, deviates most in the half-retractile condition of the talons, and the upright carriage of his body, from the true feline characters; and with these physical modifications is combined so much of the canine disposition, as enables this species to be used in packs for the purposes of the chase.

"The middle-sized cats, which lurk in the branches of trees, as the leopards, ocelots, &c., have a fulvous ground colour, broken by irregular dark spots; a marking which admirably adapts them for concealment amidst foliage. A similar relation of adaptation to the peculiar theatre of their destructive habits may be traced in other species. The tiger, for example, which prowls on the ground, and creeps stealthily towards his victim between the stems of the trees and plants of the jungle, has his bright ground colour interrupted with black vertical stripes. The lion, which traverses the parched deserts of Africa, and lies in wait to intercept the antelopes which bound in troops from one oasis to another, would be rendered too conspicuous if his tawny hide were ornamented with the stripes or spots that characterize the feline livery; the-e, therefore, which are obvious enough in the earlier periods of his existence, become obliterated as he attains to maturity. A smaller feline species, the puma, or American lion, which plays the predatory character in a corresponding theatre of the New World, presents a similar uniformity of colour. The feline animals bring forth from two to six young ones at a birth." [See **CAT: LION: TIGER: &c.**]

FENNEC. (*Megacotis*.) This is a beautiful little animal, belonging to the digitigrade Carnivora, closely allied to the Dog, principally found in N. Africa. It is about ten inches in length, five in height, and is of a yellowish-white colour: it has a pointed visage, long whiskers, large bright black eyes, and very large ears, of a bright rose colour, internally lined with long hairs, and the orifice covered with a valve or membrane; the legs and feet are like those of a dog; and

it has a taper tail. It inhabits, says Mr. Pennant, the vast deserts of Saara, which extend beyond Mount Atlas; and burrows

NUBIAN FENNEC.
(MEGALOTIS NUBIENSIS)

in sandy ground, which shows the use of valves to the ears. It is so exceedingly swift that it is very rarely taken alive; feeds on insects, especially locusts; sits on its rump; is very vigilant, and barks like a dog, but much shriller. A fine species of Fennec was lately brought alive from S. Africa, and presented to the Zoological Society of London, by Capt. Sir Edw. Belcher. There seem to be two, if not three, species.

FERÆ. The name of an order of Mammalia, to which the Cats, Dogs, Bears, &c. belong. [See CARNIVORA.]

FERRET. (*Mustela furo*.) This useful but ferocious little animal, of the weasel kind, is kept in a domesticated state in Europe, and is used for rabbit-hunting, as well as for destroying rats. In its general form it resembles the Polecat, but is rather smaller; its usual length being about thirteen inches, exclusive of the tail, which is about

FERRET. (MUSTELA FURO)

five. It has a very sharp nose, red and fiery eyes, and round ears. Its colour is a pale yellow, but it also occasionally partakes of all the colours common to the weasel kind, white, black, brown, &c. In the slenderness of its body and the shortness of its legs it also resembles the weasel. In its wild state it is a native of Africa, whence it was originally imported into Spain, and from Spain gradually introduced into other European countries. The cold of our winters is, in fact, too severe for it, so that it becomes necessary to keep it in a warm box, with wool or some other substance in which it may imbed itself. In this state it sleeps almost continually; and when awake, immediately begins to search about for food: that which

it is usually given is bread and milk, but its favourite food is the blood of smaller animals. It is by nature an enemy to the rabbit; and Buffon affirms, that whenever a dead rabbit is presented for the first time to a young Ferret, he flies upon it in an instant, and bites it with great fury; but if it be alive, he seizes it by the throat and sucks its blood. When sent into the burrows of rabbits, the Ferret is always muzzled, that he may not kill the rabbits in their holes, but only drive them out to be caught in the nets prepared for them. If the Ferret become unmuzzled he is often lost; for after sucking the blood of his victim, he generally falls asleep in the burrow, from whence he emerges only when by the calls of hunger he goes forth in pursuit of fresh prey; and there, in the midst of abundance, he continues to lead a rapacious life, till the severity of the weather proves fatal to him.

The Ferret, as we have before said, in its nature is ferocious; it is tame without attachment; and such is its appetite for blood, that it has been known to attack and even kill children in their cradles. It is of an irascible nature, and when irritated, the odour it emits is very disagreeable, and its bite not easily cured. The female has two broods in the year, each consisting of from six to nine. She not unfrequently devours her young as soon as they are born; in which case she usually has another brood very soon.

FIBER. A genus of glirine Mammalia, close to the Beaver, the only known species of which is the N. American *Ondatra*, or *Castor zibethicus*, L. [See BEAVER.]

FILANDER. The name given by Brun to the E. India Island Kangaroo, *Halmaturus Asiaticus*.

FINFOOTS. The name applied to two grallatorial birds, allied to the Coots, and closely connected with the web-footed order. One of these, *Heliornis Surinamensis*, is a native of S. America; while the other, *Podica Senegalensis*, or African Finfoot, is, as the name implies, a native of W. Africa.

FILARIA. A genus of Entozoa, having a long, slender, and thread-like body, resembling that of the *Gordii* among the Annelidæ, but with mere marks on the body instead of the rings. These parasitic animals are imbedded in the parenchyma of the cellular tissues, between the coats of the viscera, &c., often existing in numerous bundles, contained in a common cyst or tunic. They are not confined to the larger animals, but are found in insects and their larvæ, and even in various Mollusca. Of these the most common, or at all events the most dreaded by man, is the *Filaria Medinensis*, or Guinea Worm, a most troublesome animal in hot climates, where it insinuates itself under the skin, generally of the leg, and sometimes causes the most excruciating pain. At the seventh anniversary of the Microscopical Society of London, held Feb. 10. 1847, a paper was read, entitled "Observations on the Structure and Nature of the *Filaria Medinensis*, or Guinea Worm," by G. Busk, Esq. The author, before entering upon the

anatomical structure of the worm, premised a short statement of what is known with regard to its habits, and the localities in which it occurs endemically, showing that it is found only in certain portions of the torrid and north temperate zones in Africa and Asia. It is especially frequent on the coast of Africa, and thence derives its name of Guinea Worm. When perfect, its average length is from four to six feet: the body is cylindrical, and of uniform size, or nearly so, throughout; there is no anal or other opening visible at the caudal extremity of the worm, or in any part of its length. The cavity of the worm is occupied by innumerable young. In some worms, or in some parts of them, these occupy the whole space, whilst in others a grumous matter predominates, and only a few young are here and there imbedded in it. The young *Filaria* differ considerably in their outward form from the parent worm, being furnished with a long tapering tail, which constitutes about two-fifths of the length of the body. The life of *Filaria Medinensis* as a parasite extends over from twelve to eighteen months. When arrived at maturity, it comes to the surface, and is either brought away or comes away piecemeal, thus affording an opportunity for the dispersion of the vivacious young with which its interior is crammed. From these facts, the author suggested that *Filaria Medinensis*, in its parasitic form, presented an instance, among the nematoid Entozoa, of an intermediate or transitory generation, such as have been shown by several naturalists to exist in most of the lower classes of animals.

FIELDFARE. (*Turdus pilaris*.) A bird of the Thrush kind, ten inches in length, and weighing about four ounces. The head is ash-coloured, inclining to olive, and spotted with black; the back and greater coverts of the wings are of a deep chestnut; the throat and breast yellow, regularly spotted with black; the belly and thighs yellowish-white; tail dark brown; legs dusky brown; bill yellow. The Fieldfare is a migratory bird, making its appearance in this country about the beginning of October, in order to avoid the rigorous winters of the north, whence it sometimes comes in great flocks, according to the severity of the season, and leaves us about the latter end of February or the beginning of March. It builds its nest in the loftiest trees; and feeds on hips, haws, and other berries, with various kinds of worms, &c.

Mr. Knapp, speaking of the Fieldfare in his "Journal of a Naturalist," says, "In this county [Gloucestershire], the extensive lowlands of the river Severn in open weather are visited by prodigious flocks of these birds; but as soon as snow falls or hard weather comes on, they leave these marshy lands, because their insect food is covered or become scarce, visit the uplands to feed on the produce of the hedges, and we see them all day long passing over our heads in large flights on some distant progress, in the same manner as our larks, at the commencement of a snowy season, repair to the turnip fields

of Somerset and Wiltshire. They remain absent during the continuance of those causes which incited their migration; but, as the frost breaks up, and even before the thaw has actually commenced, we see a large portion of these passengers returning to their worm and insect food in the meadows, attended probably by many that did not take flight with them — though a great many remain in the upland pastures, feeding promiscuously as they can. In my younger days, a keen, unwearied sportsman, it was always observable, that in hard weather these birds increased prodigiously in number in the counties far distant from the meadow lands, though we knew not the reason; and we usually against this time provided tempting bushes of haws, preserved in a barn, to place in frequented hedges, near our secret standings. When the Fieldfare first arrives, its flesh is dark, thin, and scurfy; but, having fed a little time in the hedges, its rump and side veins are covered with fat. This is, in part, attributable to suppression of perspiration by the cold, and partly to a nutritive farinaceous food; its flesh at the time becoming bluish and clean. The upland birds are in this state, from perhaps the end of November till the end of January, according as the hedge fruit has held out; and at this period they are comparatively tame; afterwards, though the flights may be large, they become wild; and the flesh, assuming its darkness, manifests that their food has not been farinaceous. The distant foreign migrations, which have been stated to take place from the meadows of the Severn, I believe to be only these inland trips; and that the supposed migrators returned to those stations fat and in good condition, owing to their having fed during their absence on the nutritive berry of the white thorn. * * * Perfectly gregarious as the Fieldfare is, yet we observe every year, in some tall hedge-row, or little quiet pasture, two or three of them that have withdrawn from the main flocks, and there associate with the blackbird and the thrush. They do not appear to be wounded birds, which from necessity have sought concealment and quiet, but to have retired from inclination; and I have reason to apprehend that these retreats are occasionally made for the purpose of forming nests, though they are afterwards abandoned without incubation. * * * These retiring birds linger with us late in the season, after all the main flights are departed, as if reluctant to leave us; but towards the middle or end of April the stragglers unite, form a small company, and take their flight."

FILE-FISH. (*Balistes*.) There are several species which come under this general denomination; as the Unicorn File-fish, the European File-fish, and many others. The first-named, the UNICORN FILE-FISH (*Balistes monoceros*), grows to a considerable size, often exceeding two feet in length: the body is of an oval shape, and, like most others of this genus, it possesses the power of inflating at pleasure the sides of the abdomen, by means of a pair of bony processes within that part: the skin is everywhere

covered with very minute spines, and the general colour is grey, inclining to brown on the upper parts, and varied with irregular, dusky, subtransverse undulations and spots; both fins and tail are of a light brown colour, the latter marked by a few dusky bars. It is a native of the Indian and American seas, and feeds chiefly on crustaceous and testaceous marine animals. The European FILE-FISH (*Balistes capriscus*) is a species well known to the older authors as an inhabitant of the Mediterranean; and instances have occurred, though they are extremely rare, of their having been taken on our own coasts. The shape is ovate; general colour violaceous grey, sometimes variegated both on the body and fins with blue or red spots; first or small dorsal fin furnished with three or four rays, the first of which is very strong; tail rounded. The peculiar structure of the first or dorsal fin is worthy of notice: the bones or rays are so contrived to act in concert with considerable force in suddenly elevating the fin at pleasure; and how hard soever the foremost be pressed, it will not stir; but if the last be only lightly pressed, the other two immediately fall down with it; as a cross-bow is let off by pulling down the trigger. For this reason the fish is called on the Italian shores of the Mediterranean by the name of *Pesce Balestra*.

We shall describe but one more species, which is the singular species named the ACULEATED FILE-FISH (*Balistes aculeatus*). This is twelve or fourteen inches long; of a rufous brown colour, with a few purplish bands across the hinder part of the belly, and sometimes along the middle of the body; from the top of the eye to the crown four bright blue lines diverge, so as to form a blue-striped lozenge on that part; while from the bottom of the eye three or four longer lines of the same colour reach as far as the pectoral fin, the space between the lines being blackish. The skin is rough, and strongly crossed with reticular squares: on each side the end of the body three longitudinal rows of spines: tail rounded. It is a native of the Indian, American, and Red seas; varies in colour, and is sometimes of a bright golden hue.

FINCHES. A numerous group of birds, embracing not only some of the most beautiful, but also some of the most agreeable of the feathered tribe. [See **FRINGILLIDÆ**.]

FIRE-FLY. The name generally given to any insect which has the singular property of emitting a luminous secretion. [See **ELATER: GLOW-WORM: LAMPYRIS**.]

FISHING-FROG. [See **ANGEL**.]

FISSIROSTRES. The name of a tribe of Perching Birds, comprehending those which have a very wide gape, as the Swallow.

FISTULARIA. The name given to a genus of fishes, distinguished by elongated or tube-like noses and cylindrical bodies. [See **PIPE-FISH**.]

FITCHET. An animal of the weasel kind. [See **POLECAT**.]

FISH, or FISHES. (*Pisces*.) The name by which we designate the various species of a class of vertebrate animals inhabiting the water; which breathe through the medium of that fluid by means of branchiæ or gills, instead of lungs; which swim by means of fins; and are mostly covered with cartilaginous scales. Though the external form varies, by far the greater part possess considerable similarity of conformation—an elongated oval; a figure which enables them with greater celerity and ease than any other to traverse the aqueous element. They are also, for the most part, furnished with an air bladder in the interior of the body, (an oblong white membranous bag close to the backbone,) by the dilation or compression of which their specific gravity is said to be varied, and by which they are enabled to rise and sink in the water. In most osseous fishes, this organ extends along the back of the abdomen, between the kidneys and the chylipoietic viscera, and sometimes beneath the caudal vertebra to near the end of the tail. It is seldom bifurcated; still more seldom divided lengthwise into two bladders: it is oftener divided crosswise into two compartments, which intercommunicate by a contracted orifice; or are quite separate. All parts of their bodies seem adapted to accelerate their motion; their fins, their tails, and the undulation of their back bones assist progression—their whole structure, in short, being as evidently adapted for swimming as that of a bird is for flight.

The fins consist of a thin elastic membrane supported by bony rays, and are denominated, according to their position, *dorsal, pectoral, ventral, anal, or caudal*: the dorsal and ventral fins apparently serve to balance the fish, and the pectoral to push the creature forward, or to arrest its progress when required; the anal fin occupies that part which lies between the anus and the tail, and this serves to keep the fish in its upright or vertical position: but the tail, which in some fishes is horizontal, and in others perpendicular, seems to be the grand instrument of motion; the fins being all subservient to it, and only giving direction to its powerful impetus. Yet the fins are important, not only as organs of motion, but as affording by their structure, position, and number, materials for distinguishing orders, families, and genera. The surface of the body is termed naked, when destitute of scales; scaly, when furnished with them; smooth, when the scales are without angles; lubricous, when provided with a mucus; loricate, or mailed, when enclosed in a hard integument; fasciate or banded, when marked with zones from the back to the belly; tuberculate, spinous, striped, reticulate, &c.

Nature appears to have fitted this class of animals with appetites and powers of an inferior kind; and formed them for a sort of passive existence in the heavy element in which they live. To preserve their own existence, and to continue it to their posterity, fill up the whole circle of their pursuits and enjoyments; and to these they seem impelled rather by necessity than choice.

Their senses are incapable of making any nice distinctions; and they move forwards in pursuit of whatever they can swallow, conquer, or enjoy. A craving desire of food seems to give the ruling impulse to all their motions. This appetite impels them to encounter every danger; and to their rapacity no bounds appear prescribed. Even when taken out of the water, and almost expiring, they greedily swallow the very bait which lured them to destruction. Their digestive powers seem, in some measure, to increase with the quantity of food they consume; and a single pike has been known to devour a hundred roaches in three days. The amazing digestive faculties in the cold maws of fishes have justly excited the curiosity of philosophers, and have effectually overturned the system of those who maintain that the heat of the stomach is a sufficient instrument for digestion. The truth seems to be, that there is a power of animal assimilation lodged in the stomachs of all creatures, which we can neither describe nor define, converting the substances they swallow into a fluid adapted for their peculiar support. This is effected neither by trituration, by warmth, by motion, by a dissolving fluid, nor by their united efforts; but by some principle in the stomach yet unknown, which acts in a manner very different from all kinds of artificial maceration. The food taken into the stomach is often seen, though nearly digested, still to retain its original form; and, in fact, is ready for a total dissolution, while to the eye it appears yet untouched by the force of the digestive powers. But though the appetites of Fishes are insatiable, no animals can endure the want of food so long.

Professor Owen, in his 'Lectures on Comparative Anatomy,' observes, "A few species retain the primitive vermiform type, and have no distinct locomotive members; and these members, in the rest of the Pisces class, are small and simple, rarely adapted for any other function than the propulsion or guidance of the body through the water. The form of the body is, for the most part, such as mechanical principles teach to be best adapted for moving with least resistance through a liquid medium. The surface of the body is either smooth and lubricous, or is covered by closely imbricated scales, rarely defended by bony plates or roughened by hard tubercles; still more rarely armed with spines. The central axis of the nervous system presents but one partial enlargement, and that of comparatively small size, at its anterior extremity, forming the brain, which consists of a succession of simple ganglionic masses, most of them exclusively appropriated to the function of a nerve of special sense. The power of touch can be but feebly developed in fishes. The organ of taste is a very inconspicuous one, the chief function of the trunk-work supporting it, or the hyoidian apparatus, relating to the mechanism of swallowing and breathing. Of the organ of hearing there is no outward sign; but the essential part, the acoustic labyrinth, is present, and the semicircular canals largely developed within the laby-

rinth is without cochlea, and is rarely provided with a special chamber, but is lodged, in common with the brain, in the cranial cavity. The eyes are usually large, but are seldom defended by eyelids, and never served by a lachrymal organ. The alimentary canal is commonly short and simple, with its divisions not always clearly marked, the short and wide gullet being hardly distinguishable from the stomach. The pincere, for the most part, retains its primitive condition of separate caecal appendages to the duodenum. The heart consists essentially of one auricle, and one ventricle, receiving the venous blood, and propelling it to the gills; whence the circulation is continued over the entire body in vessels only, which are aided by the contraction of the surrounding muscular fibres. The blood of fishes is cold; its temperature being rarely elevated above that of the surrounding medium."

"All writers on animal mechanics," observes the able Professor just quoted, and to whom we are indebted for the following detached extracts, "have shown how admirably the wriggle form of the fish is adapted to the element in which it lives and moves: the viscera are packed in a small compass, in a cavity brought forwards close to the head, and whilst the consequent abrogation of the neck gives the advantage of a more fixed and resisting connection of the head to the trunk, a greater proportion of the trunk behind is left free for the development and allocation of the muscular masses which are to move the tail. In the caudal, which is usually the longest, portion of the trunk, transverse processes cease to be developed, whilst the dorsal and intercalary spines shoot out from the middle line above and below, and give the vertically extended, compressed form, most efficient for the lateral strokes, by the rapid alternation of which the fish is propelled forwards in the diagonal, between the direction of those forces." "You may be reminded that all the vertebrae of the trunk are distinct from one another at one stage of the quadruped's development, as in the fish throughout life; and you might suppose that the absence of that development and confluence of certain vertebrae near the tail, to form a sacrum, was a mark of inferiority in fishes. But note what a hindrance such a fettering of the movements of the caudal vertebrae would be to creatures which progress by alternate vigorous inflections of a muscular tail. A sacrum is a consolidation of a greater or less proportion of the vertebral axis of the body, for the transference of more or less of the weight of the body upon limbs organized for its support on dry land; such a modification would have been useless to the fish, and not only useless, but a hindrance and a defect."

"The pectoral fins, those articulated prototypes of the fore-limbs of other vertebrata, with the last segment, or hand, alone projecting freely from the trunk, and swathed in a common undivided tegumentary sheath, present a condition analogous to that of the embryo buds of the homologous members in the higher vertebrata. But what would

have been the effect if both arm and forearm had also extended freely from the side of the fish, and dangled as a long flexible many-jointed appendage in the water? This higher development, as it is termed, in relation to the prehensile limb of the denizen of dry land, would have been an imperfection in the structure of the creature which is to cleave the liquid element: in it, therefore, the fore limb is reduced to the smallest proportions consistent with its required functions: the hrachial and antibrachial segments are abrogated, or hidden in the trunk: the hand alone projects, and can be applied, when the fish darts forwards, prone and flat, by flexion of the wrist, to the side of the trunk; or it may be extended at right angles, with its flat surfaces turned forwards and backwards, so as to check and arrest more or less suddenly, according to its degree of extension, the progress of the fish; its breadth may also be diminished or increased by approximating or divaricating the rays. In the act of flexion, the fin slightly rotates and gives an oblique stroke to the water. For these functions, however, the hand requires as much extra development in breadth, as reduction in length and thickness; and mark how this is given to the so-called embryo or rudimental forelimb: it is gained by the addition of ten, twenty, or it may be even a hundred digital rays, beyond the number to which the fingers are restricted, in the hand of the higher classes of Vertebrata. We find, moreover, as numerous and striking modifications of the pectoral fins, in adjustment to the peculiar habits of the species in Fishes, as we do in the fore limbs in any of the higher classes. This fin may wield a formidable and special weapon of offence, as in many Siluroid fishes. But the modified hands have a more constant secondary office, that of touch, and are applied to ascertain the nature of surrounding objects, and particularly the character of the bottom of the water in which the fish may live. You may witness the tactile action of the pectoral fins when gold fish are transferred to a strange vessel: their eyes are so placed as to prevent their seeing what is below them: so they compress their air-bladder, and allow themselves to sink near the bottom, which they sweep, as it were, by rapid and delicate vibrations of the pectoral fins, apparently ascertaining that no sharp stone or stick projects upwards, which might injure them in their rapid movements round their prison." * * * "Everywhere, whatever resemblance or analogy we may perceive in the ichthyic modifications of the Vertebrate skeleton to the lower forms or the embryos of the higher classes, we shall find such analogies to be the result of special adaptations for the purpose or function for which that part of the fish is designed.

"The ventral fins or homologues of the hind legs are still more rudimental—still more embryonic, having in view the comparison with the stages of development in a land animal—than the pectoral fins; and their small proportional size reminds the homologist of the later appearance of the

hind limbs, in the development of the land Vertebrate. But the hind limbs more immediately relate to the support and progression of an animal on dry land than the fore limbs: the legs are the sole terrestrial locomotive organs in Birds, whose fore-limbs are exclusively modified, as wings, for motion in another element. The legs are the sole organ of support and progression in Man, whose pectoral members or arms are liberated from that office, and made entirely subservient to the varied purposes to which an inventive faculty and an intelligent will would apply them. To what purpose, then, encumber a creature, always floating in a medium of nearly the same specific gravity as itself, with hind limbs? They could be of no use; nay, to creatures that can only attain their prey, or escape their enemy, by vigorous alternate strokes of the hind part of the trunk, the attachment there of long flexible limbs would be a grievous hindrance, a very monstrosity. So, therefore, we find the All-wise Creator has restricted the development and connections of the hind limbs of Fishes to the dimensions and to the form which, whilst suited to the limited functions they are capable of in this class, would prevent their interfering with the action of more important parts of the locomotive machinery."

"The following short account of some experiments upon fish, made for the purpose of ascertaining the use of their fins, I give (says Mr. Owen) in the words of their gifted describer, PALEY, to whom Comparative Physiology owes many beautiful accessions to its teleological applications. 'In most fish, beside the great fin—the tail, we find two pairs of fins upon the sides, two single fins upon the back, and one upon the belly, or rather between the belly and the tail. The balancing use of these organs is proved in this manner. Of the large-headed fish, if you cut off the pectoral fins, that is, the pair which lies close behind the gills, the head falls prone to the bottom; if the right pectoral fin only be cut off, the fish leans to that side; if the ventral fin on the same side be cut away, then it loses its equilibrium entirely; if the dorsal and anal fins be cut off, the fish reels to the right and left: when the fish dies, that is, when the fins cease to play, the belly turns upwards. The use of the same parts for motion is seen in the following observation upon them when put into action. The pectoral, and more particularly the ventral fins, serve to raise and depress the fish: when the fish desires to have a retrograde motion, a stroke forward with the pectoral fin effectually produces it; if the fish desire to turn either way, a single blow with the tail the opposite way sends it round at once; if the tail strike both ways, the motion produced by the double lash is progressive, and enables the fish to dart forwards with an astonishing velocity. The result is not only in some cases the most rapid, but in all cases the most gentle, pliant, easy animal motion with which we are acquainted. However, when the tail is cut off, the fish loses all motion, and it gives itself up to where the water

impels it. The rest of the fins, therefore, so far as respects motion, seem to be merely subsidiary to this. In their mechanical use the anal fin may be reckoned the keel; the ventral fins outriggers; the pectoral fins the oars; and if there be any similitude between these parts of a boat and a fish, observe that it is not the resemblance of imitation, but the likeness which arises from applying similar mechanical means to the same purpose."

"Professor Müller concludes, from his experiments, 'that the air-bladder in fishes, in addition to other uses, serves the purpose of increasing by resonance the intensity of the sonorous undulations communicated from water to the body of the fish.' The vibrations thus communicated to the peri- and endo-lymph of the labyrinth are doubtless made to beat more strongly upon the delicate extremities of the acoustic nerve, in osseous fishes, by their effect upon the suspended otoliths, also relate to the medium through which the sonorous vibrations are propagated to the fish, and to the mode in which they are transmitted to the organ; in like manner as the eye-balls are expanded in order to take in the utmost possible amount of light. The contracted encephalon harmonises with and suffices for the sensations and volitions, and the simple series of ideas daily repeated in the monotonous existence of the scaled inhabitants of the waters. To say that the fish's ears and eyes were made enormous in order to strike strongly on its dull brain—that the development of the organs of sense has been exaggerated to compensate for the defective size of their nervous centres—implies a want of due appreciation of the beautiful adjustment of the labyrinth and eyeball to the conditions under which the fish receives its impressions of the sonorous and luminous undulations."

It would be impossible, unless we devoted very considerable space to the subject, to enter into all the minutiae respecting the anatomy, physiology, and habits of Fishes; and sufficient for the purposes of this work, it is hoped, will be found in the descriptions which are given of the various species belonging to this large class of animals. We shall therefore conclude, with a few general observations, derived from different authors. In every point of view Fishes appear inferior to terrestrial animals; in the simplicity of their conformation, in their senses, and in their enjoyments; but theirs is an uniform existence, their movements are without effort, and their lives without labour: their bodies, instead of experiencing the rigidity of age, which is the cause of natural decay in land animals, still continue increasing with fresh supplies; and as their bodies grow, the conduits of life furnish their stores in greater abundance. How long a Fish, which seems to have hardly any bounds prescribed to its growth, continues to live, is not ascertained; but we have sufficient evidence of the extraordinary age of some Fishes. Their fecundity is, however, much more extraordinary than their longevity. Some produce their young alive; others are

oviparous: the former are the least prolific, and yet they produce in amazing abundance; the viviparous bienny, for instance, produces two or three hundred at a time. Those which exclude their progeny in eggs, and are obliged to leave them to chance, at the bottom of shallow water, or floating on the surface, where it is deeper, are much more prolific; the stock being in some measure proportioned to the danger there is of its consumption. Mr. Harnier, in the Philosophical Transactions, vol. 57., and recently, Mr. Jesse, have each given a Table, showing the different degrees of fecundity in several kinds of fish: they correspond in almost every instance; it is therefore fair to presume that the one is derived from the other.

Fish	Weight.	Weight of Spawn.	Number of Eggs.
	oz. dr.	lbs.	
Carp	25 5	2,571	205,109
Codfish	-	12,540	3,686,760
Flounders	24 4	2,200	1,357,400
Herring	5 10	480	36,960
Mackerel	18 0	1,223	546,681
Perch	8 9	765	23,323
Pike	50 4	5,100	49,304
Roach	10 6	361	81,558
Smelt	2 0	149	38,278
Sole	14 8	542	100,362
Tench	40 0	-	383,252
Lobster	-	1,671	21,699

To which he adds, "The Salmon is far more productive than any of these; the ovum of one female salmon will produce 20,000,000 eggs."

"That fish have the power of hearing, there can, I think, be no doubt, as I have seen them suddenly move at the report of a gun, though it was impossible for them to see the flash. They also appear to have the sense of smelling, as they will prefer paste and worms that have been prepared with particular perfumes. They have also some curiosity, which I have witnessed by putting some new object into the water, which they have assembled around, and appeared to reconnoitre: carp, especially, would come up to a new fish which was put amongst them. Roach, and other small kinds, are perfectly aware of, and are careful to avoid, those fish which prey upon them. Thus, I have seen large carp swim amongst a shoal of roach without in the least disturbing them, while, if a pike comes near them, they make off in every direction. Fish appear, also, to be capable of entertaining affection for each other. I once caught a female pike during the spawning season, and nothing could drive the male away from the spot at which the female disappeared, whom he had followed to the very edge of the water."

"It may be considered as a law," observes Mr. Yarrell, that those Fish which swim near the surface of the water have a high standard of respiration, a low degree of muscular irritability, great necessity for oxygen, die soon—almost immediately when

taken out of the water, and have flesh prone to rapid decomposition: mackerel, salmon trout, and herrings are examples. On the contrary, those fish that live near the bottom of the water have a low standard of respiration, a high degree of muscular irritability, and less necessity for oxygen; they sustain life long after they are taken out of the water, and their flesh remains good for several days."

In "The Zoologist," (p. 705, *et seq.*) there is an article of considerable interest, entitled "Notes on the Nidification of Fishes," by R. Q. Couch, Esq., from which the following passages are extracted:

"We have been accustomed to look on the inhabitants of the deep as devoid of any thing like intelligence or affection; as beings guided solely by insatiable appetites, which lead them indiscriminately to prey on each other, and to abandon their offspring to the mercy of the sea and their predatory companions, from the instant that the ova are shed. Any attempt to dispel this opinion will probably be received with distrust; for, taken as a whole, fish are certainly the most universally predaceous of any class of animals in existence; being checked only by want of power. But notwithstanding this, some, at least, have a redeeming quality, and show a remarkable care and anxiety for their young. Nests are built in which the ova are deposited, and over which the adult fish will watch till the young make their escape. And where circumstances will not allow of this continued care, as from the reflux of the sea, the old fish will return with the return of the tide, and remain as long as the water will permit.

"During the summers of 1842 and 1843, while searching for the naked molluscs of the county, I occasionally discovered portions of sea-weed, and the common coralline (*C. officinalis*), hanging from the rocks in pear-shaped masses, variously intermingled with each other. On one occasion, having observed that the mass was very curiously bound together by a slender silky-looking thread, it was torn open, and the centre was found to be occupied by a mass of transparent amber-coloured ova, each being about the tenth of an inch in diameter. Though examined on the spot with a lens, nothing could be discovered to indicate their character. They were, however, kept in a basin, and daily supplied with sea-water, and eventually proved to be the young of some fish. The nest varies a great deal in size, but rarely exceeds six inches in length, and four inches in breadth. It is pear-shaped, and composed of sea-weed, or the common coralline, as they hang suspended from the rock. They are brought together, without being detached from their places of growth, by a delicate opaque white thread. This thread is highly elastic, and very much resembles silk, both in appearance and texture: this is brought round the plants, and tightly binds them together, plant after plant, till the ova, which are deposited early, are completely hid from view. This silk-like thread is passed in all directions through and around the mass in a very complicated

manner. At first the thread is semi-fluid, but by exposure it solidifies; and hence contracts and binds the substances, forming the nest so closely together, that it is able to withstand the violence of the sea, and may be thrown carelessly about without derangement. In the centre are deposited the ova, very similar to the masses of frog-spawn in ditches.

"It is not necessary to enter into the minute particulars of the development of the young, any further than by observing that they were the subject of observation, till they became excluded from the egg, and that they belonged to the fifteen-spined Stickleback (*Gasterosteus Spinachia*). Some of these nests are formed in pools, and are consequently always in water; others are frequently to be found between tide-marks, in situations where they hang dry for several hours during the day; but whether in the water, or liable to hang dry, they are always carefully watched by the adult animal. On one occasion I repeatedly visited one every day for three weeks, and invariably found it guarded. The old fish would examine it on all sides, and then retire for a short time; but soon return to renew the examination. On several occasions I laid the eggs bare, by removing a portion of the nest; but when this was discovered, great exertions were instantly made to recover them. By the mouth of the fish the edges of the opening were again drawn together, and other portions torn from their attachments, and brought over the orifice till the ova were again hid from view. And as great force was sometimes necessary to effect this, the fish would force its snout into the nest as far as the eyes, and then jerk backwards till the object was effected. While thus engaged, it would suffer itself to be taken in the hand, but repelled any attack made on the nest, and quitted not its post so long as I remained. And to those nests that were left dry between tide-marks, the guarding fish always returned with the returning tide, nor did they quit the post to any great distance till again carried away by the receding tide.

"* * * But fish vary a great deal in the mode of what may be called their incubation, as much as any other class of animals. Thus, some of the sharks produce their young alive, and in a state quite ready for active life; while others, with the rays, deposit eggs very similar, physiologically, to birds' eggs, which are known as mermaid's purses, being frequently to be found cast on shore on most beaches. Also, among the pipe fishes (*Synbranchia*) of our own seas, we have instances of marsupial fish, as perfect as the kangaroo is marsupial among quadrupeds. But the formation of nests and the watchful attention of fish over their young, which I have repeatedly seen, are unsuspected points of great beauty in their history, and give to them a higher degree of intelligence and interest than we have been accustomed to award. But, from their living in the almost boundless ocean, and wandering where they cannot be observed by man, their habits and economy have been but slightly studied, and they have suffered in reputation accordingly.

But those finer traits of character, which we are so much accustomed to admire in the higher animals, from their being constantly before our eyes, are not found wanting even among fish.

"Aristotle," says Baron Cuvier, in his "Lectures on the History of the Natural Sciences," "in his account of fishes, is truly admirable, giving proof of knowledge on many points superior to our own. Amongst the facts which he relates, many are still in doubt; however, from time to time, new observations teach us the justice of some of his assertions, even of those which seem the most hazardous. He says, for example, that a fish named *Physic* makes a nest like birds. For a long time the thing was treated as a fable; however, very recently, M. Olivé discovered that a fish named the Goby (*Gobius niger*) has similar habits. The male, in the season of love, makes a hole in the sand, surrounds it with fucus, making a true nest, near which his mate waits, and he never leaves his post till the eggs which have been deposited in it are hatched." [The most extensive general work on Fishes is by Cuvier and Valenciennes, while in this country the works of Sir John Richardson, and Messrs. Yarrell and Lowe, are well worthy of study.]

FLAMINGO. (*Phœnicopterus*.) This is one of the most remarkable of all the aquatic birds for its size, beauty, and, as some say, also for the delicacy of its flesh. The body of the Flamingo is smaller than that of the Stork; but, owing to the great length of the neck and legs, it stands nearly five feet high; and measures six feet from the point of the beak to the tip of the claws. The head is small and round, and furnished with a bill nearly seven inches long, which is higher than it is wide, light and hollow, having a membrane at the base, and suddenly curved downwards from the middle. The long legs and thighs of this bird are extremely slender and delicate, as is also the neck. The plumage is not less remarkable than its figure, being of a bright scarlet. The young differ greatly from the adult, changing their plumage frequently, and which does not become fully coloured till the third year. Flamingoes inhabit the warm climates of Asia, Africa, and America: they live and migrate in large flocks, frequenting desert sea-coasts and salt marshes. They are extremely shy and watchful: while feeding, they keep together, drawn up artificially in lines, which at a distance resemble those of an army; and, like many other gregarious birds, they employ some to act as sentinels, for the security of the rest. On the approach of danger, these give warning by a loud sound, like that of a trumpet, which is the signal for the flock to take wing; and when flying they form a triangle.

Their food appears to be molluscous animals, spawn, and insects, which they fish up by means of their long neck, turning their head in such a manner as to take advantage of the crook in their beak. Their nest is of a singular construction: it is formed of mud in the shape of a hillock, with a cavity at the top, and of such a height as to admit of

the bird's sitting on it, or rather standing, her long legs being placed one on each side at full length; thus situated, the female generally lays two or three white eggs somewhat larger than those of a goose. The young do not fly until they have nearly attained their full growth, though they can run very swiftly a few days after their exclusion from the shell. In some parts these birds are tamed, principally for the sake of their skins, which are covered with a very fine down, and applicable to all purposes for which those of the swan are employed. When taken young, they soon grow familiar; but they are not found to thrive in the domesticated state, as they are extremely impatient of cold, and apt to decline from the want of their natural food. They are caught by snares, or by making use of tame ones. There are two species: 1. *Phœnicopterus antiquorum*; which is of a rose colour, with red wings, the quills being black: these inhabit the warm regions of the old continent, migrating in summer to southern, and sometimes to central Europe: these beautiful birds were much esteemed by the Romans, who often used them in their grand sacrifices and sumptuous entertainments; and such of the luxurious emperors as wished to indulge in the very excess of epicurism, were wont to gratify their guests with a dish of Flamingos' tongues! 2. *Phœnicopterus ruber*; deep red; with black quills; which are peculiar to tropical America, migrating in the summer to the southern, but rarely to the middle states.

Some interesting particulars of this species are given by Mr. Gosse's correspondent, Mr. Hill, who observes that when he visited the island of Cuba he had excellent opportunities of noticing their habits—that he was much among the marshes and swamps where the floods of the river and the sea form lakelets, and successively deposit their stores of living atoms, with the rising and falling tides. "Here the Flamingos flock and feed. They arrange themselves in what seem to be lines, in consequence of their finding their food along the edges of these shallows; and though it is true that whilst their heads are down, and they are clattering with their bills in the water, they have one of their number on the watch, standing erect, with his long neck turning round to every point, ready to sound the alarm on the apprehension of danger,—what appears to be a studied distribution of themselves back to back, as some observers describe their arrangement, is nothing but their regardlessly turning about in their places, inwardly and outwardly, at a time when all are intent on making the most of the stores which the prolific waters are yielding." Speaking of a pair of Flamingos which had been captured, and were kept on board the vessel he was in on the coast, he says, "I was struck with their attitudes, with the excellent adaptation of their two-fold character of waders and swimmers; to their habits, while standing and feeding in the sort of shoal which we made them in a large tub upon deck. We were here able to observe their natural gait and action. With a firm erectness, like a man treading a wine-press,

they trod and stirred the mashed hiseulits, and junked fish, with which we fed them; and plied their long lithe necks, scooping with their heads reversed, and bent inwardly towards their trampling feet. The bill being crooked, and flattened for accommodation to this reversed mode of feeding, when the head is thrust down into the mud-shoals and the sand drifts, the upper bill alone touches the ground. The structure of the tongue, of which Professor Owen has given so minute and interesting a description, is admirably adapted for a mode of feeding altogether peculiar. The spines with which the upper surface is armed, are arranged in an irregular and alternate series, and act with the notches on the edge of the upper mandible, on which they press when the bird feeds with the head reversed. In this reversed position, the weight and size of the tongue becomes a very efficient instrument for entrapping the food. The bird maddles, and elutters the bill, and dabbles about, and the tongue receives and holds as a strainer whatever the water offers of food. There is nothing of the Heron character in the Flamingo. Extraordinary length of neck and legs is common to both, but a firm erect posture is its ordinary standing attitude. The neck is never curved inward and outward, convex and concave, like a Crane's, but its movements are in long sweeping curves, which are peculiarly pleasing, when the bird is preening its plumage."

FLEA. (*Pulex irritans*.) The common Flea, a troublesome insect of the order *Aphaniptera*, is well known in every quarter of the globe for its agility, its caution, and its invincible pertinacity in feasting on the blood of man and various animals. Like the major part of the Insect race of other tribes, the Flea is produced from an egg, in the form of a minute worm or larva, which changes to a chrysalis, in order to give birth to the perfect animal. The female drops her eggs, at distant intervals, in any favourable situation: they are very small, of an oval shape, of a white colour, and a polished surface. From these, in the space of six days, are hatched the larvæ, which are destitute of feet, of a lengthened, worm-like shape, beset with distant hairs; the head furnished with a pair of short antennæ, and the tail with a pair of slightly curved forks or holders; their colour is white, with a reddish cast, and their motions quick and tortuous. In the course of ten or twelve days they attain their full growth, and are then nearly a quarter of an inch long: at this period they cease to feed, and, casting their skin, change to an oval-shaped chrysalis, exhibiting the immature limbs of the included insect, which in twelve days emerges in its perfect form: in winter, however, the time required for this evolution is considerably more. It now begins to exert its lively motions, and employs its sharp proboscis in obtaining nourishment from the juices of the first bird or quadruped to which it can gain access. Nothing can exceed the polished elegance of the shelly armour with which the Flea is covered, or the elasticity

of its surprising leaps. When examined with a microscope it will be observed to have a small head, large eyes, and a roundish body: it has two short hairy antennæ, composed of five joints; and at a small distance beneath these is the proboscis, which is strong, sharp-pointed, tubular, and placed between a pair of jointed guards or sheaths. Its suit of sable armour appears to be neatly jointed, and beset with a multitude of sharp spines. Its legs are six in number; the joints of which are so adapted, that it can fold them up one within another, and in leaping they all spring out with prodigious force. [See CUREOE.]

FLITTERMOUSE. [See BAT.]

FLOUNDER. (*Pleuronectes flesus*.) A well-known flat-fish, very similar to the Plaice, but generally smaller and of more obscure colours; the upper side being of a dull brown, and the under of a dull white: the body is covered with very small scales, and along the back runs a row of small sharp spines: the tail is slightly rounded. The Flounder is an inhabitant of the Northern, Baltic, and Mediterranean seas; it is also very common about our own coasts: and it even frequents our rivers at a great distance from the salt water. Though inferior to some others of the genus, its flesh is in considerable esteem.

FLOUNDER.—PLEURONECTES FLEBUS.

The **ARGUS FLOUNDER** (*Pleuronectes Argus*) is a very elegant species, native of the American seas, and of the same general form with the Turbot. It is of a yellowish white colour on the upper side, marked by numerous eye-shaped spots, consisting of bright blue circles with yellow centres: the whole skin is also marked both on the body and fins with small blue and brown specks, and is covered with small scales: the under side is of a whitish or pale gray colour: the lateral line is arched over the pectoral fins, and is thence continued straight to the tail, which is rounded at the tip.

FLUKE. [See FASCIOLE, p. 228.]

FLUSTRA. A genus of *Bryozoa*, or *ellio-branched Molluscs*, having the general aspect of *Zoophytes*, but lately regarded as belonging to a much higher group. The name is derived from the Saxon *Flustrian*, to weave: hence they are familiarly termed *sea-mats*. They consist of calcareous branches, sometimes forming leaves or stems, with numerous cells, united in clusters like a honeycomb. The aperture of the cells is formed by a semicircular lid, convex externally and concave internally, which folds

down when the polypus is about to advance from the cell; and, it is said, the lid of the cells opens and shuts without the slightest perceptible synchronous motion of the polyp. Some species have cells on one side of the leaves only. In the most plant-like of them there is no substance in the least

LEAF-LIKE SEA-MAT.—(FRUSTRA FOLIAEAE.)

resembling that of the plants with which they agree most in form, nor is there any substance similar to theirs in the most analogous of the true vegetables; they are often, however, called "white sea-weeds." In Dr. George Johnstone's admirable "History of British Zoophytes," we read as follows: "When recent it exhales a pleasant scent, which Pallas compares to that of the orange, Dr. Grant to that of violets, and which a friend tells me smells to him like a mixture of the odour of roses and geranium. On the contrary, Mr. Patterson tells me that the smell is strong, peculiar, and disagreeable. It probably varies, and is often not to be perceived at all."

From the same authentic source we derive the following information respecting another species, *Frustra membranacea*: the cells of which are oblong, with a short blunt spine at each corner. It is thus described:—"Polypidom forming a gauze-like incrustation on the frond of the sea-weed, spreading irregularly to the extent of several square inches, in general thin and closely adherent, but sometimes becoming thickish, and then capable of being detached in considerable portions; cells very obvious to the naked eye, oblong, quadrangular, with a blunt hollow spine at each angle." In many specimens there are some anomalous processes, a quarter of an inch in height, scattered over the surface: they arise from within the cells, are simple, horny, and tubular, but closed at top. When the polypes are all protruded, they form a beautiful object under the microscope, from their numbers, their delicacy, the regularity of their disposition, and the vivacity of their motions, now expanding their tentacula into a beautiful campanulate figure, now contracting the circle, and ever and anon retreating within the shelter of their cells. The tentacula are numerous, filiform, white, and in a single series. The Rev. David Landsborough has seen a specimen (and I have seen its equal, Dr. J. remarks) of *F. membranacea* five feet in length by eight

inches in breadth. "As every little cell had been inhabited by a living polype, by counting the cells on a square inch, I calculated that this web of silvery lace had been the work and the habitation of above two millions of industrious and, we doubt not, happy inmates; so that this single colony on a submarine island was about equal in number to the population of Scotland." [See BRITOZOA in SUPPLEMENT.]

FLY. A name of very general application to insects furnished with wings; but properly restricted to the numerous genus *Musca*. The strong resemblance which exists among all the species of the Fly tribe, together with their small size, makes it difficult to discriminate them readily; but the general and most obvious character of Flies, by which they are distinguished from other winged insects, is in their having transparent and naked wings, totally free from the farina or dust visible on those of butterflies, and in having no cases or covers for them. Thus, by this simple character, they are clearly distinguished from the butterfly, the beetle, the grasshopper, &c. The principal parts or members of which Flies are composed are the head, the thorax, the body, and the wings; from the number of the latter the most obvious distinction for a systematic arrangement of them is drawn. [See MUSCIPIDAE.]

FLY-CATCHERS. (*Muscicapidae*.) This very numerous family, which receives its popular name from the expertness of the individuals composing it in catching the flying insects upon which they feed, is found widely diffused throughout both the eastern and western continents; and includes many of the most beautiful of the feathered tribes. The general habits of the Flycatchers are those of the shrikes, and, according to their size, they prey on small birds or insects. They have the beak horizontally depressed and armed with bristles at its base, with the point more or less decurved and emarginated. Those which are called "Tyrant Flycatchers" (*Tyrannus*) are American birds, of a large size and very spirited; they have a long, straight, and very stout bill; the ridge of the upper mandible straight and blunt, its point abruptly hooked; while the species which inhabit Europe, and come under the denomination of "Restricted Flycatchers" (*Muscicapa*), have shorter bristles at the gape, and the bill much more slender, though still depressed, with an acute edge above, and the point a little curved downward. There are, however, only two small species which inhabit this country.

THE GRAY or SPOTTED FLYCATCHER. (*Muscicapa grisola*.) This bird is nearly five inches and three quarters in length; bill broad, flattened, and wide at the base, where it is beset with a few short bristles; a ridge runs along the upper mandible; both that and the under one are dusky at the tips, and the latter is yellowish towards the base: all the upper plumage is of a mouse colour, darkest on the wings and tail; head and neck more or less obscurely spotted with

dark brown; the wing-coverts, secondary quills, and scapulars, also dark brown, edged with dingy white; under parts very pale ash, tinged with rufous on the sides and breast, the latter being marked with

SPOTTED FLYCATCHER.
(MUSCICAPA GRISOLA)

streaks of brown: the legs are short, and darkish. Of all our summer birds the Flycatcher is the most mute. It visits this island in the spring, and disappears in September. The female builds her nest commonly in gardens, on any projecting stone in a wall, or on the end of a beam, screened by the leaves of a vine, sweet-briar, or woodbine, and sometimes close to the post of a door, where people are going in and out all day long. The nest is rather carelessly made of moss and dried grass, mixed in the inside with some wool and a few hairs. She lays four or five eggs, of a dull white, closely spotted and blotched with rusty red. This bird feeds on insects, for which it sits watching on a branch or a post, suddenly dropping down upon them, and catching them on the wing, and immediately rising, returns again to its station to wait for more. After the young have quitted the nest, the parent birds follow them from tree to tree, and watch them with the most sedulous attention. They feed them with the flies which flutter among the boughs beneath; or, pursuing their insect prey with a quick irregular kind of flight, like that of a butterfly, to a greater distance, they immediately return as before described.

Mr. Knapp says, "We have perhaps no bird more attached to peculiar situations than the Grey Flycatcher (*Muscicapa grisola*); one pair, or their descendants, frequenting year after year the same hole in the wall, or the same branch on the vine or the plum. I once knew a pair of these birds bring off two broods in one season from the same nest. This Flycatcher delights in eminences. The naked spray of a tree, or projecting stone in a building, or even a tall stick in the very middle of the grass-plot, is sure to attract its attention, as affording an uninterrupted view of its winged prey; and from this it will be in constant activity a whole summer's day, capturing its food, and returning to swallow it."

The PIED FLYCATCHER. (*Muscicapa luteosa*.) This species is found in Sweden,

Russia, and sometimes in this country; its distribution here, however, being almost confined to "the lakes" in the north of England. The beak is black; the forehead white; crown of the head, and all the upper parts, black: the lesser wing-coverts and the greater coverts of the primaries are dusky; the first six quills are wholly dusky, the rest white at the base: the under parts of the bird are white; the tail is dusky black; and the legs are black. There is, however, occasionally great variety in their markings. It frequents wild and uncultivated tracts of furze, and open heaths; and constructs its nest in the hole of a tree. The female lays five very pale blue eggs.

The RED-EYED FLYCATCHER. (*Muscicapa olivacea*.) This species is a native of the southern provinces of North America, and is also found in many of the West India islands, particularly Jamaica, where it is called *Whip-Tom-Kelly*, from a fancied resemblance of its note to those words. The head, neck, and back are olive brown; the wing-coverts and quills are edged with green, as is also the tail; the feathers dull brown above and greyish beneath: from the beak passing over the eyes and terminating on the hind head is a reddish white line: the under parts of the body are pale white, irregularly spotted with pale yellow; beak and feet brown.

Mr. Gosse, in describing this species in his "Birds of Jamaica," says he can scarcely understand how the call can be written *Whip-Tom-Kelly*, as the accent is most energetically on the last syllable. The familiar name which he gives to it is *John-to-whit*; and says that sounds closely resembling those words are uttered by this bird with incessant iteration, and untiring energy from every grove, nay almost from every tree. Its food, he observes, is both animal and vegetable; for in its stomach he has found seeds of the Tropic birch, and the berries of sweet-wood, and has also observed it jumping out from its umbrageous retreat after stationary, as well as vagrant, prey. "Incubation takes place in June and July. The nest is rather a neat structure, though made of coarse materials. It is a deep cup, about as large as an ordinary ten-cup, narrowed at the mouth; composed of dried grass, intermixed with silk-cotton, and, springily, with Hellen and spiders' nests, and lined with thatch-threads. It is usually suspended between two twigs, or in the fork of one, the margin being overwoven, so as to embrace the twigs. This is very neatly performed. Specimens vary much in beauty. The eggs, commonly three in number, are delicately white, with a few small red-brown spots thinly scattered over the surface, sometimes very minute and few."

The CAYENNE FLYCATCHER. (*Tijra Cayanensis*.) A beautiful species, above seven inches in length, which inhabits Cayenne and St. Domingo. The crown of the head is a brown yellow; and from the beak, which is dusky, to the hind part of the head, is a white streak: all the upper parts of the

body are brown, the feathers lighter on their margins; the wing-coverts and the upper ones of the tail are brown, their edges rufous; the chin is white, and the rest of the under parts bright yellow: quills and tail brown.

PARADISE FLYCATCHER. (*Muscipeta Paradisi*.) A singular bird, measuring upwards of twenty inches long, owing to its disproportioned tail, which is generally about fourteen inches. Its head, hind part of the neck, and throat, are greenish black; the feathers on the former are very long, and form a crest: the back, rump, wing-coverts, and tail-feathers are white; the greater coverts and quills black, fringed with white; the fore part of the neck, and all the under parts of the body, pure white; tail cuneiform; legs ash-coloured. This bird is found in the southern parts of Africa, frequenting the borders of rivers, where its insect food is most abundant.

SWALLOW-TAILED FLYCATCHER. (*Muscivora forficata*.) This bird, whose distinctive appellation is derived from its forked tail, is ten inches in length, of which the tail forms one half. The colour of the beak is black; the head and back are light grey, slightly tinged with red; the under parts of the body white; beneath the wing red; the wing-coverts ash-colour; and the quills black, edged with gray. It inhabits Mexico. [See *TYRANNUS: RHINIDUKA: ONYCHORHYNCHUS.*]

FLYING-FISH. (*Exocetus*.) By the extraordinary length and size of their pectoral fins, the fishes of this genus are enabled to spring occasionally from the water, and to support a kind of temporary flight through the air: hence their name. It is evident, however, that their "flights" are chiefly performed for the purpose of escaping from the jaws of the dolphin, and other predaceous fishes, which are constantly pursuing them. Mr. Gosse, in his admirably graphic "Naturalist's Sojourn in Jamaica," has shown that they can direct and change their flight. The following account cannot, therefore, be entirely depended on: "I have never," observes Mr. G. Bennett, the author of "Wanderings in New South Wales," "been able to see any

FLYING-FISH. — (*EXOCETUS VOLITANS*)

percussion of the pectoral fins during flight, and the greatest length of time I have seen this volatile fish on the fin has been thirty seconds by the watch, and their longest flight mentioned by Captain Hall has been 200 yards; but he thinks that subsequent observation has extended the space. The most usual height of flight, as seen above the surface of the water, is from two to three

feet; but I have known them come on board at a height of fourteen feet and upwards; and they have been well ascertained to come into channels of a line-of-battle ship, which is considered as high as twenty feet and upwards. But it must not be supposed they have the power of elevating themselves in the air after having left their native element; for, on watching them, I have often seen them fall much below the elevation at which they first rose from the water, but never in any one instance could I observe them rise from the height at which they first sprang; for I regard the elevation they first take to depend on the power of the first spring or leap they make on leaving their native element."

In tropical seas the Flying-fish rise from water in flocks, or, more properly, shoals, of hundreds at a time, when disturbed by the passing of a ship, or pursued by their inveterate foe, the dolphin. They spring from the crest of a wave, and, darting forward, plooge into another, to wet the membrane of the fins, and in this manner continue their flights for several hundred yards, often pursued by marine birds in the element to which they are driven for protection against the tyrants of their own. — Gardner, in his "Travels in Brazil," confirms Humboldt's assertion, (denied by Cuvier,) that the Flying-fish uses its pectoral fins as wings during the time it remains above water.

The distinguishing characters of the genus are — pectoral fins nearly equal to the body in length; head flattened above and on the sides; the lower part of the body furnished with a longitudinal series of carinated scales on each side; dorsal fin placed above the anal; eyes large; jaws furnished with small pointed teeth. There are but very few of the genus.

The MEDITERRANEAN FLYING-FISH (*Exocetus exilis*.) runs from ten to fifteen inches in length, its general shape resembling that of a herring: the head is rather large, and sloping pretty suddenly in front; the eyes large, and of a silver colour, with a cast of gold; the scales are large, thin, and rounded; and the whole fish is of a bright silvery cast, with a blue or dusky tinge on the upper part. The pectoral fins are of a sharply lanceolate form, and extend as far as the beginning of the tail; the dorsal and anal fins are shallow, and placed opposite each other near the tail, which is deeply forked with sharp-pointed lobes, the lower being nearly twice the length of the upper; the ventral fins, which are rather large and long, are situated behind the middle of the body.

OCEANIC FLYING-FISH. (*Exocetus volitans*.) This species is somewhat more slender, and the head less sloping than the preceding, though from its general resemblance it might be easily mistaken for it; but the principal difference arises from the ventral fins being seated near the pectoral ones, and from their being much smaller and of a slightly lunated form. This species is of a bright silver colour, gradually deepening into purplish brown on the back, the dorsal and anal yellowish, and the ventral fins and

tail reddish. It is a native of the Indian and American seas; but it is also sometimes found in the Mediterranean, and some solitary instances occur of its having been seen about our own coasts. In the Gulf of Mexico are found some species with curious appendages or filaments attached to the lower jaw. The air-bladder in this, and doubtless in the rest of the genus, is very large.

FLYING SQUIRREL. (*Pteromys*.) A genus of rodent mammalia, distinguished from the common Squirrels by the extension of the skin of the flank between the fore and hind legs, which gives them the power of supporting themselves a short time in the air, and of making immense leaps. The feet have long bony appendages, which help to support this lateral membrane. To this genus belongs the common Flying Squirrel (*Pteromys volans*), which is chiefly found in the most northern regions, and abounds in the birch and pine woods of Siberia in particular. Its colour on the upper parts is a pale grey, and on the under parts milk-white. It measures about six inches and a quarter in length, from the nose to the tail, the latter being shorter than the body, thickly furred, of a slightly flattened form, and rounded at the extremity. Its manner of flight, or rather springing, is performed by means of an expansile furry membrane, reaching from the fore feet to the hind; and in order the better to manage this part, the thumb of the fore feet is stretched out to a considerable length within the membrane, so as to appear in the skeleton like a long bony process on each side of the fore feet. The Flying Squirrel generally resides in the hollows of trees towards the upper part; preparing its nest of the finer mosses. It is a solitary animal, and is only seen in pairs during the breeding season. It rarely makes its appearance by day, emerging only at the commencement of twilight, when it may be seen climbing about the trees, and darting with great velocity from one to the other. It feeds on the young buds and catkins of the birch and pine, &c.; and in the winter it leaves its nest only in mild weather, but does not become torpid during that season. This animal readily springs, or, as it were, swiftly sails, to the distance of twenty fathoms or more, and thus passes from one tree to another, always directing its flight obliquely downwards. It very rarely descends to the surface, and, when taken and placed on the ground, runs or springs somewhat awkwardly, with its tail elevated, beginning to climb with great activity as soon as it reaches a tree. If thrown from a height, it immediately spreads its membranes, and, balancing it-self, endeavours to direct its motion by the assistance of the tail. The young are produced early in May, and are from two to four in number: they are at first blind, and nearly void of hair; and the parent fosters them by covering them with her flying-membrane. In their manner of sitting and feeding, as well as in the notion of washing their face with their paws, &c., the Flying Squirrel resembles the common species.

THE VIRGINIAN FLYING SQUIRREL. (*Pteromys volucella*.) This species differs from the preceding both in size and colour. Its general length is five inches to the tail, which measures about four inches; the colour being a subferruginous brown above, and yellowish

VIRGINIAN FLYING SQUIRREL.
(*PTEROMYS VOLUCELLA*.)

white beneath; and the edges of the flying-membrane are of a darker tinge than the rest of the fur, contrasting with the white border of the under part. The tail is of a similar colour to the body, with the hair spreading towards each side, and the extremity somewhat sharpened. The eyes are large, and the ears rather short, almost naked, and slightly rounded. It is a native of the temperate parts of North America; and, being a beautiful little animal and readily tamed, is frequently kept in a state of captivity: it feeds on various fruits, nuts, almonds, &c., and shows a considerable degree of attachment to its possessor. It is naturally of a gregarious disposition, and may be seen flying, to the number of ten or twelve together, from tree to tree. Like the former species, it is chiefly nocturnal in its habits: it prepares its nest in the hollows of trees, with moss, leaves, &c.; several often inhabiting the same retreat. They are capable of swimming, in case of necessity, in the manner of other quadrupeds, and, after leaving the water, can exert their power of flight as before.

FOOTMAN [MOTHS]. A name given by collectors to different species of Moths, of the genera *Euleptia* and *Lithosia*.

FORAMINIFERA. A term equivalent to the *Rhizopoda* of some naturalists, and signifying a class of minute animals provided with many-chambered cells. [See RHIZOPODA in SUPPLEMENT.]

FORFICULA. [See EARWIG.]

FORMICA. [See ANT.]

FORMICIDÆ. A family of Hymenopterous insects, composed of the well-known and highly interesting tribes of *Ants*; but not including the still more singular *Termite*, or *White Ants* (with which they must not be confounded). Both are full of interest, and worthy of the most careful investigation; and to each we have accordingly devoted no inconsiderable space. [See ANT: DRAGON-ANT.]

FOSSANE. (*Viverra fossa*.) An animal of the Weasel tribe, nearly allied to the Genet, which it greatly resembles: its colours, however, are somewhat bolder, and its rows of spots along the sides more regularly disposed: the under part of the body is of a dingy white; and the tail is annulated with black and white. This animal is said to be possessed of considerable fierceness, destroying poultry, &c., in the manner of the common weasel. It is a native of Madagascar, Guinea, Cochín-China, &c.

FOSSQUES. An extensive group of Hymenopterous insects, forming a subsection of the *Aculata*. They are solitary in their habits; and most of the species are organized for excavating cells in earth or wood, in which they bury other insects in a wounded and feeble state, and at the same time deposit their eggs; so that the larvæ, when hatched, find a store of food prepared for their sustenance. The basal joint of the posterior tarsi not being enlarged, the legs are not fitted for carrying pollen, neither is the body clothed with hairs, requisite for its transport. Some species, the structure of whose legs is not adapted for burrowing, are parasitic, and, like the cuckoo among birds, lay their eggs in the nests of other species, at whose expense the young are reared. When full grown, these larvæ spin a cocoon, in which they pass the pupa state. The perfect insects are generally very active, and fond of the nectar of flowers, especially those of the Umbellifera. The work of Mr. W. E. Shuckard on the British Fossorial Hymenoptera is very highly esteemed by Entomologists, and we recommend it to those desirous of studying the British species, often endowed with such wonderfully interesting habits.

FOWL. This term, when taken in a general sense, is of similar import with Birds; but, in a limited view, it more peculiarly signifies the larger kind of birds, both wild and domestic, which are either reared or pursued for the purposes of food. In this sense, Fowl includes all the denizens of the poultry yard, with pheasants, partridges, and all other kinds of winged game.

FOX. (*Canis vulpes*.) Of all beasts of prey, the Fox is considered to be the most crafty and sagacious, whether in obtaining food or in eluding pursuit. They appear to be pretty generally diffused throughout all the northern and temperate parts of the

head, obliquely seated eyes, sharp erect ears, an elongated body well covered with hair, proportionally short limbs, and a straight bushy tail, so long that when pendent it touches the ground. The general colour is a yellow-brown; and on the forehead, shoulders, hind part of the back, as far as the beginning of the tail, and outside of the hind legs, it is a little mixed with white or ash-colour: the lips, cheek, and throat are white, and a white stripe runs along the under side of the legs; the tips of the ears and the feet are black: the tail a reddish-yellow, mixed with a blackish tinge, and internally brownish yellow-white, with a blackish cast; the tip milk white.

The Fox varies considerably in size, but in general measures about three feet six inches from the snout to the end of the tail, of which the latter is sixteen inches; and the height at the shoulders is about fourteen inches. "The general expression of its features," as Mr. Bell remarks, "the obliquity and quickness of the eye, the sharp shrewd-looking muzzle, and the erect ears, afford the most unequivocal indications of that mingled neutence and fraud which have long rendered it a by-word and a proverb; for it is well-known that this character of its physiognomy is not falsified by the animal's real propensities and habits."

The Fox prepares for himself a convenient den in which he lies concealed during the greater part of the day: this he sometimes obtains by dispossessing the badger of his hole; at other times by forming his own burrow; but it is always so contrived as to afford the best security to the occupant, by being situated under hard ground, the roots of trees, &c., and is furnished with proper outlets through which he may escape when hard pressed by his hunters. Prudent, patient, and vigilant, he waits the opportunity of depredation, and varies his conduct on every occasion. His domicile is generally at the edge of a wood, and yet within a convenient distance of some farm-house: from thence he listens to the crowing of the cock, and the cackling of the domestic fowls; then, concealing his approaches, he creeps stealthily along, attacks his prey, and seldom returns without his booty. Poultry, pheasants, partridges, small birds, leverets, and rabbits are his favourite objects: but he is also fond of certain berries and fruits, and can occasionally make a meal of field-mice, frogs, newts, &c. The Fox seems to be wholly devoid of that instinct of gratitude which characterizes the Dog, and is even found in the Wolf and Jackal; nay, whatever kindness may be shown him when in a state of confinement, he is still sly, timid, and suspicious; insusceptible, as it would seem, of any kind of attachment. His voice is a kind of yelp, or stifled bark, and his bite is very severe and dangerous.

There is no animal that affords more diversion to the huntsman, or that gives him more occupation, than the Fox. When he finds himself pursued, he usually makes for his hole, and, penetrating to the bottom, lies quiet till a terrier is sent in to him; but

FOX. — (*CANIS VULPES*.)

globe; occurring with numerous varieties, as to colour and size, in most parts of Europe, the north of Asia, and America. The Fox has a broad head, a sharp snout, a flat fore-

should his den be under a rock or the roots of trees, he is safe, for the tenier is no match for him there, and he cannot be dug out. When, as is generally practised, the retreat to his den is cut off, his stratagem and shifts to escape are various. He always seeks the most woody parts of the country, and prefers such paths as are most emburressed by thorns and briars: he runs in a direct line before the hounds, and at no great distance from them; and when overtaken, he defends himself with desperate and silent obstinacy. The fetid odour of the Fox is intolerable: his sight is keeo; and he possesses astonishing aculeeness of snell. The time of gestation is about sixty-three days; and while the female is suckling her young, nothing can exceed her courage and boldness. The Fox, unmolested, will live twelve or fourteen years. In the first year he is called a *cub*; the second, a *Fox*; and the third, an *old Fox*: he is eighteen months, or nearly two years old, before he arrives at full maturity. The skio makes a warm and soft fur, and is therefore used for muffs, liaiugs, &c.

ARCTIC FOX. (*Canis lagopus*.) This species is smaller than the common Fox, with a sharp nose, and short rounded ears, almost hid in its fur; the legs are short, and the toes are covered both above and below with a very thick soft fur: the tail is shorter than that of the common Fox, but more bushy. It inhabits the countries bordering on the Frozen Ocano in both continents. At the approach of winter their coat of hair becomes thick and ragged; till at length it grows perfectly white, changing colour last on the ridge of the back and tip of the tail.

ARCTIC FOX — (*CANIS [VULFES] LAGOPUS*.)

This species preys upon various small quadrupeds, such as hares, marmots, &c., as well as upon all kinds of water-fowl and their eggs; also, when necessity urges, on the carcase of fish left on shore, shell-fish, or whatsoever the sea throws up. Mr. Pennant says, that in Spitzbergen and Greenland, where the ground is eternally frozen, they live in the clefts of rocks, two or three inhabiting the same hole. They swim well, and often cross from island to island in search of prey. They are tame and inoffensive animals; and are killed for the sake of their skins, both in Asia and Hudson's Bay:

but though the fur is light and warm, it is not durable. The Greenlanders take them either in pitfalls dug in the snow, and baited with fish; or in springs made with whale-bone laid over a hole made in the snow, streved over at bottom with fish; or in traps similarly baited. The metric travellers and voyagers, Dr. Sir John Richardson, Captains Parry, Franklin, Ross, Lyon, Back, and Simpson, refer much in their narratives to this inhabitant of snow-covered countries; and those familiar with their writings cannot but sympathize with their regard for the limited number of animals and plants which they met with in these dreary wastes. One of the most active, and certainly one of the prettiest, was the White Arctic Fox described above.

ANTARCTIC FOX. (*Canis Antarecticus*.) This species is found to the Falkland Isles, near the extremity of South America, and is about one-third larger than the Arctic Fox; has much the appearance of the wolf in its ears, tail, and the strength of its limbs; whence the French call it *Loup-venard*, or the Wolf-fox. The head and body are of a cinereous brown hue, the hair being more woolly than that of the commoo Fox; the legs are dashed with rust-colour; the tail dusky, more bushy, and shorter than that of the commoo Fox, and tipped with white. It resides near the shores, kenuels like the rest of its kind, and forms regular paths from one bay to another, probably for the convenience of surprising water-fowl, oo which it principally subsists. It is a tame, fetid animal, and barks like a dog.

BLACK or SILVERY FOX. (*Canis argentatus*.) This species inhabits the northern parts of Asia, Enrope, and America, and is only distinguishable from the commoo Fox

SILVERY FOX. — (*CANIS ARGENTATUS*.)

by its copious and beautiful fur, which, particularly in the Asiatic one, is of a rich and shining black or deep brown colour, with the longer or exterior hairs of a silvery white, giving a highly elegant appearance to the animal, and rendering its fur more valuable than that of almost any other quadruped.

RED FOX. (*Canis fulvus*.) This species is found throughout North America; its general colour is bright ferruginous on the head, back, and sides; beneath the chin it is white, whilst the throat and neck are of a dark grey: the under parts of the body towards the tail are a very pale red. The skins are much sought for, and employed in various manufactures.

CROSSED FOX. (*Canis decussatus.*) The colour of this animal's fur is a sort of gray, resulting from the mixture of black and white hair. He has a black cross on his shoulders, from which he derives his name. The muzzle, lower parts of the body, and the feet are black; the end of the tail is white. It inhabits the northern parts of America; and it has been suggested as probable that it is only a variety of the Black Fox.

CORSAC FOX. (*Canis Corsac.*) This animal, which inhabits the vast plains of Tartary, is, in summer, of a clear yellow-ferruginous colour: in winter, mixed or shaded with grey, deeper on the back, white on the belly, and reddish on the feet: the eyes are surrounded with a border of white; and a brownish stripe runs from them down the nose: the ears are short; the tail almost as long as the body, both the base and tip being blackish. It commits great ravages among the game; is hunted with falcons and dogs; and it is said that not less than forty or fifty thousand are annually taken, sold to the Russians, and a vast number of them sent into Turkey.

SWIFT FOX. (*Canis velox.*) This beautiful little animal, which is much smaller than any other species, is distinguished by its extraordinary speed, which, it is asserted, surpasses the fleetest antelope, and seems rather to fly than touch the ground in its course. Its body is slender, and the tail rather long, cylindrical, and black: the hair is fine, dense, and soft.

FOX-HOUND. Among those manly and exhilarating field sports for which "Old England" has so long been famous, fox-hunting justly claims pre-eminence; and in the annals of the chase numerous instances of speed, courage, and perseverance are to be found which may well be ranked among the marvellous. With this part of the subject, however, we have no legitimate business, but merely allude to it, in order to account for the extraordinary care and attention which, for centuries, have been bestowed on this peculiar breed of dogs—a breed in which are combined, in the highest possible degree of excellence, fleetness, strength, spirit, fine scent, perseverance, and subordination. The Fox-hound is much smaller than the Stag-hound, his average height being from twenty to twenty-two inches; but in all the requisites for hunting he is unrivalled. To be perfect, we are told, "his legs should be straight as arrows; his feet round and not too large; his shoulders black; his breast rather wide than narrow; his chest deep; his back broad; his head small; his neck thin; his tail thick and bushy, and well carried."

FRANCOLIN. The birds which are thus designated bear so great a resemblance to the Partridge, that many naturalists include them in the genus *Perdix*; but there are others who say that the Francolins are distinguished from the Partridges by the beak being longer and stronger; the tail is also longer, &c. In the manners of the

birds also there is a great dissimilarity, the Francolins residing in damp places and perching upon trees, whereas Partridges always rest upon the ground.

The **COMMON FRANCOLIN** (*Francolinus vulgaris*) is upwards of twelve inches in length: the upper parts of the head, hind part of the neck, back, and wing-coverts are varied with dusky and yellowish rust-colour; the sides of the head, neck, breast, and belly are black; round the neck is a rusty orange collar; the sides of the neck, breast, and body are black, varied with spots of white; the lower part of the belly and thighs striped with black; the lower part of the back and rump crossed with alternate lines of black and yellowish white: the quills dusky, marked with transverse rusty yellow spots: tail rounded, the four middle feathers alternately striped with black and rusty yellow; the others on each side, with black and white for two-thirds of their length: the rest black to the tip: legs reddish, and furnished with a spur. This elegant species is found throughout all the warmer parts of Europe; other allied species are met with in Bengal, and are abundant in Barbary and other parts of Africa. It feeds upon insects and seeds: it has a very loud whistle; and its flesh is greatly esteemed.

The **PONDICHERY FRANCOLIN** (*Francolinus Pondicerianus*) is a beautiful species. Its length, including the tail, is fourteen inches: the beak is red at the base and yellow at the tip: the top of the head is gray-brown; the forehead bright red, that colour passing over the eyes like an eyebrow, and ending on the back of the head: the breast is alternately striped with whitish-yellow and bright brown: the back, the greater and lesser wing-coverts, and the rump, gray-brown; the edges of the feathers with black spots, and all of them with three reddish-white stripes: the quills and secondaries are gray, the outer webs striped with yellowish white: the two middle tail-feathers are gray, spotted, and crossed with four yellow-white bands; the belly and abdomen are white, striped with semicircular bands: the legs are red, and armed with a strong spur. It is met with in parts of India, where it frequents gardens and cultivated lands, and is called a partridge.

The **PEARLEN FRANCOLIN.** (*Francolinus perlatius.*) This species is common in China, and is likewise known at Bengal, the Mauritius, and Madagascar. Like the rest of the Francolins, it is a forest bird, and perches upon trees. The male of this beautiful species varies from ten to twelve inches in length: the feathers on the top of the head are black, edged with red; two longitudinal black stripes commence from the beak, and surround the eyes, leaving the space between pure white, of which colour the throat is also: the feathers on the hinder part of the neck are black, marked with four longitudinal white spots; those on the top of the back, the fore part of the neck, the breast, and the lesser wing-coverts, are black, each

varied with six rounded white spots: the scapulars are of a reddish chestnut, with whitish spots at their tips: the back, the rump, the upper wing-coverts, and those of the tail at their base, are black, with innumerable white bands; the tip of the tail-feathers is black; the belly is whitish, the sides rather red, both varied with black lines: the under tail-coverts are red; the beak is black, and the feet are bright red: the tarsi are armed with a thick and blunt spur. The female is rather smaller, and differs in several respects from the male.

FRATERCULA. A genus of web-footed birds belonging to the family *Alcedæ*, and containing the common Puffin (*F. arctica*.) [See PUFFIN: AUK.]

FRIAR-BIRD. (*Tropidorhynchus corniculatus*.) This bird is generally dispersed over New South Wales, where it is variously called by the colonists Friar-bird, Monk, and Poor Soldier. It selects the topmost dead branches of the most lofty trees whereon

FRIAR-BIRD.
(*TROPIDORHYNCHUS CORNICULATUS*.)

to perch and pour forth its garrulous and singular notes, and attracts attention more by its loud and singular call than by its appearance. It is called, from some of these notes, Poor Soldier, Pimlico, Four o'clock, &c.: its bare head and neck give it also the appellation of Friar-bird, Monk, and Leather-head. Its flight is undulating and powerful, and it may be seen passing from one part of the forest to another: when among the branches it can cling in every direction; sometimes it hangs by one foot, with its head downwards: if seized when wounded it can inflict with its sharp claws severe wounds on the head of the captor. It feeds on the pollen of Eucalypti, on insects, wild figs, and berries. It begins to breed in November, becoming then animated and fierce, readily attacking hawks, crows, and other birds that may venture near its nest. The nest is cup-shaped, and rather rudely constructed, being composed of the inner rind of the stringy bark and wool, to which succeeds a layer of fine twigs, lined with grasses and fibrous roots; the whole openly suspended to the horizontal branch of an apple (*Angophora*) or gum-tree, frequently within a few feet of the ground. The eggs are generally three in number. The young have merely the rudiment of a knob to the bill. — (*Gould's Birds of Australia*.)

Another species, *TROPIDORHYNCHUS AR-
GENTICERS*, or Silvery-crowned Friar-bird,
inhabits the north-west coast of Australia.

FRIGATE-BIRD. (*Tachypetes*.) This is an aquatic bird allied to the Cormorants, from which, however, it differs by having a forked tail, short feet, the membranes of which are very deeply notched, an extraordinary spread of wing (said to be ten or twelve feet in extent), and a beak both man-

FRIGATE-BIRD. — (*TACHYPETES AQUILA*.)

dibles of which are curved at the tip. The plumage is a richly-empurpled black, the under part of the throat more or less varied with white, and the beak red. In command of wing it is equalled by none of its class; and it is accordingly met with at an immense distance from all land, principally between the tropics, where it is seen darting upon the flying-fish, and attacking the gannets and gulls in order to make them disgorge their prey. It has received from English sailors the names of Frigate-bird and Man-of-war bird. It breeds on trees on uninhabited islands, and lays a single spherical white egg.

Dr. Chamberlaine, in the *Jamaica Almanac* for 1843, thus writes of the Frigate-bird: "He is almost always a constant attendant upon our fishermen, when pursuing their vocation on the sand-banks in Kingston harbour, or near the Palisados. Over their heads it takes its aerial stand, and watches their motions with a patience and perseverance the most exemplary. It is upon these occasions that the Pelicans, the Gulls, and other sea-birds, become its associates and companions. These are also found watching with equal eagerness and anxiety the issue of the fishermen's progress, attracted to the spot by the sea of living objects immediately beneath them. And then it is, when these men are making their last haul, and the finny tribe are fluttering and panting for life, that this voracious bird exhibits his fierce and voracious propensities. His hungry companions have scarcely secured their prey by the side of the fishermen's canoes, when with the lightning's dart they are pounced upon with such violence, that, to escape its rapacious assaults, they readily in turn yield their hard-earned booty to this formidable opponent. The lightness of its trunk, the short tarsi, and vast spread of wing, together with its long, slender, and

forked tail, all conspire to give him a superiority over his tribe, not only in length and rapidity of flight, but also in the power of maintaining itself on outspread pinions in the regions of his aerial habitation amidst the clouds; where, at times, so lofty are its soarings, its figure becomes almost invisible to the spectator in this nether world."

FRINGILLIDÆ. A large family of Passerine birds, known by the general name of *Finches*, and including various minor groups, consisting of several genera, more or less closely related to one another. None of them are of large size; and in their habits and general appearance they bear a very strong relationship. They feed chiefly upon various kinds of grain and seeds; occasionally also upon insects. They are for the most part hardy birds, and do not quit this country during the winter; but some few are driven hither at that season from more northern climates. Many of the *Fringillidæ* are remarkable for their powers of song; others are highly prized for the delicacy of their flesh. They frequent fields, groves, hedgerows, and woodlands; while many, in a state of captivity, are rendered subservient to the amusement and gratification of man. They are severally described in this work, and will be found in their alphabetical order. In this place we shall merely give one species, as an example, which we find among the beautifully coloured specimens in Mr. Gould's superb work. It is called *Estrelita Temporalis*, or the **RED-EYED BROWN FINCH**. This bird has the crown of the head bluish-gray; wings and tail olive-brown; patch over the eye and rump, crimson; bill red; legs yellowish white. Eggs five or six in number, of a beautiful fleshy white. It is found in the pasture lands of New South Wales and South Australia, and is particularly abundant in the neighbourhood of Sydney. In the autumn it is gregarious, often assembling in very large flocks; but in the spring they are mostly seen in pairs. They build a large nest, formed of dead grass, lined with thistle-down, in any low bush adapted for a site, and in none more frequently than in that beautiful plant, the *Leptospermum squarrosum*. In the extensive and admirable work by Messrs. Gray and Mitchell, "the Genera of Birds," the forms and figures of many of the *Fringillidæ* are described and given. It will be seen by an inspection of that work, or a glance at the large collection of them in the British Museum, or any similar place, how impossible it is for us to enumerate in this place even a tithe of the genera of birds known to naturalists. [See **BULLFINCH**, **BUNTING**, **GOLDFINCH**, **LINNET**, **CANARY-BIRD**, &c. &c.]

FRITILLARY (BUTTERFLY). A name given by insect collectors to various species of Butterflies, of the genera *Nemobius*, *Melipotis*, and *Argynnis* [which see].

FROG. (*Rana*.) Of all the Reptile tribes none are better known than those termed **ANUROUS BATRACHIANS**, including the genus *Rana*, or common Frog. In co-

lour this animal varies considerably, but its general tinge is olive-brown, variegated on the upper parts of the body and limbs with irregular blackish spots; those on the limbs being mostly disposed in a transverse direction: it has also a long dirty brown patch under each eye. The under parts are of a pale greenish-yellow cast, and much more obscurely spotted and variegated than the upper surface. It is not unfrequently seen, however, especially towards the close of summer, of a much brighter cast, and with more vivid variegations; but, like all other species which are in the habit of casting the skin, it differs at intervals as to the brightness or intensity of its colours. The teeth are very small; the eyes large and brilliant, and surrounded with a yellow circle; the ears are placed behind them, and covered with a membrane. Their muscles are considerable in relation to their bulk, and peculiarly elastic, strong, irritable, and sensible to the action of galvanism. The Frog is light, active, and lively; the limbs admirably calculated for the peculiar motions of the animal, and the hind feet strongly webbed, to assist its progress in the water, to which it occasionally retires during the heats of summer, and again during the frosts of winter: for at that time it lies in a torpid state, either deeply plunged in the soft mud at the bottom of stagnant waters, or in the hollows beneath their banks, till it is awakened from its slumber by the return of spring. And here it may be observed, that though the Frog and the Toad have a general similitude, their distinguishing characteristics are very marked and decided. The Frog leaps; the Toad crawls. The Frog is in general the smaller of the two, of a brighter colour, and has a more polished surface; the toad is brown, rough, and dusky. The Frog is light and nimble; the toad slow, corpulent, and heavy. In their internal conformation the difference is not remarkable, except that the Frog has more air-bladders than the toad, by which it is rendered better adapted for an aquatic life.

Some time in March the Frog usually deposits its ova or spawn, consisting of a clustered mass of gelatinous transparent eggs, in each of which is embedded the embryo, or tadpole, in the form of a round black globule. In this state it lies for a month or five weeks, before the tadpoles are hatched from it; during which period each egg gradually enlarges in size, and a few days before the time of exclusion the young animals may be perceived to move about in the surrounding gluten. When first hatched, they feed on the remains of the gluten in which they were imbedded, and in the space of a few days, if narrowly examined, they will be found to be furnished, on each side of the head, with a pair of ramified branchiae, or temporary organs, which again disappear after a certain space. These Tadpoles are so perfectly unlike the animals in their complete state, that a person inco- versant in natural history would hardly suppose them to bear any relationship to the Frog, since, on a general view, they appear to consist merely of head and tail; the former

large, black, and roundish; the latter slender, and bordered with a very broad transparent flamy margin. Their motions are extremely lively, and they are often seen in such vast numbers as to blacken the whole water with their legions. When the tadpoles have arrived at the age of about five or six weeks, the hind legs make their appearance; gradually increasing in length and size; and, in about a fortnight afterwards, are succeeded by the fore legs, which are indeed formed beneath the skin much sooner, and are occasionally protruded and again retracted by the reptile through a small foramen on each side of the breast, and are not completely stretched forth till the time just mentioned. It now partakes of the form both of a frog and a lizard; which figure it retains for about six hours; and then the tail continuing to decrease, it becomes quite obliterated in the space of a day or two afterwards. The Frog, at length arrived at its perfect state, is now seen wandering about the brinks of its parent waters, and sometimes in such vast numbers in particular spots, that not only has their appearance given rise to an absurd belief among the vulgar that it occasionally "rained frogs," but various modes of accounting for so "extraordinary a phenomenon" have presented themselves to the minds of those whose duty it was to dispel the unfounded though popular credulity, by tracing its origin and properly explaining it.

The Frog, no longer of ambiguous form, now feeds on animal food; by supporting itself on insects, small snails, worms, &c. It principally lives on insects, for the more readily obtaining of which the structure of its tongue is extremely well calculated; being very long, and so situated that the root is attached to the fore rather than to the hind part of the mouth; and, when at rest, lying backwards, as if the animal were swallowing the tip. By this means it is enabled to throw it some distance from the mouth, which is done with great celerity, the lipid and glutinous tip securing the prey, which is swallowed with an instantaneous motion, so quick as to be scarcely perceptible.

The muscular system of the Frog deserves particular attention. Mr. Broderip observes, "In the Anurous Batrachians, the Frogs especially, the muscles of the abdomen are more developed than in the other Reptiles: offering in this particular some analogy to the abdominal structure of the Mammifers. But it is in the disposition of the muscles of the thigh and leg in the Frogs and other Anurous Batrachians, that the greatest singularity is manifested. These, whether taken conjointly or singly, present the greatest analogy with the muscular arrangement of the same parts in Man. We find the rounded, elongated, conical thigh, the knee extending itself in the same direction with the thigh-bone, and a well-fashioned calf to the leg, formed by the belly of the *gastrocnemii* muscles. It is impossible to watch the horizontal motions of a Frog in the water, as it is impelled by these muscles and its webbed feet, without being struck by the complete resemblance in this portion of its frame to

human conformation, and the almost perfect identity of the movements of its lower extremities with those of a man making the same efforts in the same situation. By the aid of these well-developed lower limbs, and the prodigious power of their muscular and bony levers, a Frog can raise itself in the air to twenty times its own height, and traverse at a single bound, a space more than fifty times the length of its own body." The difference of sex in these animals is not perceptible till they have arrived at their fourth year, nor do they begin to propagate till they have reached that period. Hence, on comparing their slow growth with their other limitations, it would seem that they live about twelve years; but so numerous are their enemies, both by land and water, that it is probable very few arrive at so great an age. The Frog is extremely tenacious of life, and will survive for a considerable space the loss of many of its organs. If confined entirely under water, it is still enabled to support its existence for several days: on the contrary it is not so well able to endure the want of water, nor long exposure to a dry air and a hot sun, though it delights to bask occasionally in a moderate sunshine: it is therefore particularly careful to secure a retreat where it may enjoy the benefit of shade and a sufficient supply of moisture. Frogs are distinguished by a peculiar cry, termed *croaking*, particularly during rain and hot weather, in the morning and evening.—There are several other species of Frogs, a few of which it will be necessary to describe.

The EDIBLE FROG (*Rana esculenta*), so called from its being the kind most approved of for the table by our nearest continental neighbours,—is found plentifully in France, Italy, Germany, and many other parts of Europe, though it is rare in England. It is rather larger than the common Frog, and of an olive-green colour, distinctly and strongly marked on the upper parts of the body with black spots or patches, the limbs being transversely marked with bands of the same colour; and from the tip of the nose down the whole length of the back run three distinct yellow stripes. The under parts of the body and limbs are of a dull white, slightly tinged with green, and variegated with brown spots.

EDIBLE FROG. (*RANA ESCULENTA*.)

The proportion of the limbs is nearly the same as in the common Frog, and the hind feet are very strongly palmated; but the head is rather larger and more pointed. The Edible Frog is a very voracious animal, and will occasionally seize on young birds, mice, &c., swallowing them whole, like the rest of its prey. The male of this species, during

the breeding season, is observed to protrude from each side of its head a large inflated globular vesicle, and croaks so loud as to be heard at a vast distance: in fact, where these animals assemble in large numbers, their noise is most unpleasant and annoying.

The **BULL-FROG** (*Rana pipiens*) is the largest species of the genus, being three or four inches broad, and from six to eight in length without including the feet; with the limbs extended it measures about eighteen inches. It inhabits North America, particularly the southern parts of the United States; and has received the name of Bull-Frog from its voice resembling the distant lowing of a bull. Its colour on the upper parts is a dusky olive, somewhat irregularly marked with numerous dark brown spots; the under parts being of a whitish cast tinged with green, and thickly spotted. The fore feet have only four toes, and are unwebbed, but the hind feet, which are large and long, are very widely webbed. The irides of the eyes are red, surrounded with a narrow border of yellow: the external membranes of the ears are large and round, of a reddish brown colour, and surrounded by a pale yellow or whitish margin. In Mr. Catesby's Natural History of Carolina, we are told that this species frequents springs only, where, by the continual running of the water a small pond or hole is usually made before the mouth of the spring, which is rarely without a pair of these Frogs, who when surprised, with a long leap or two enter the mouth of the spring, where they are secure. He adds, that it is commonly believed that they keep the springs clean, and purify the water, and therefore the general prejudice is in their favour, although they are great devourers of young ducks and goslings, which they often swallow whole.

The **ANGUS FROG** (*Rana ocellata*) is also a native of several parts of North America, choosing moist situations, as the neighbourhood of springs and rivulets. In size it differs but little from the Bull-Frog, except that the limbs are thicker and stouter; but the feet are unwebbed, and are all divided into five toes, each joint being furnished beneath with a kind of tubercle or process. Its colour is a pale reddish brown, with two distinctly marked whitish elevated lines running down the middle of the back, the intervening space being marked with several broad fasciæ of a reddish chestnut colour, while the sides are beautifully ornamented with several ocellated or eye-shaped spots, each being half surrounded by an iris-like paler space or crescent. The limbs are elegantly banded with chestnut-coloured stripes: the under parts are of a dull white. In its general manners it is said to resemble the preceding. [For the Tree Frog, see **HYLA**.]

FROGHOPPER. (*Aphrophora spinaria*.) The popular name of a small but singular Homopterous insect, belonging to the *Cercopidae* family. They pass their whole lives on plants, on the stems of which their eggs are laid in the autumn. The following summer

they are hatched, and the young immediately perforate the bark with their beaks, and begin to imbibe their sap. Of this they take in such quantities, that it oozes out of their bodies continually, in the form of little bubbles, which soon completely envelope the insects; and from this circumstance the name of *Cuckoo-spits* is also very commonly applied to them. They thus remain entirely buried and concealed in large masses of foam, until they have completed their final transformation. When the pupa, which is of a beautiful green colour, is about to undergo its change into the complete insect, it ceases to absorb any longer the juices of the plant, and to discharge the projecting froth. It then emerges from its concealment. The winged insect is scarcely larger than the larva; but its colour is brown, with a pair of broad, irregular, pale bands across the upper wings. It possesses the power of leaping in a remarkable degree; for which purpose, the tips of their hind thighs are surrounded with little spines, and the first two joints of their feet have a similar coronet of spines at their extremities. Their thorax projects somewhat between the basis of the wing-covers; their bodies are rather short, and their wing-covers are almost horizontal and quite broad across the middle, which, with the shortness of their legs, gives them a squat appearance.

FULGORA: FULGORIDÆ. A genus and family of insects bearing great resemblance to the *Cicadidæ*. Many of them are distinguished by a curious prolongation of the forehead, the shape of which varies extremely in the different species, which in tropical regions are numerous. The legs are in general fitted for leaping, with large spurs; and the males are destitute of those organs which are employed in the *Cicadæ* for the production of sounds. We should observe, that Kirby and Spence, on the authority of Stedman's Surinam, assert that *Fulgora lateranaria* makes a loud noise in the evening, like that made by a razor-grinder, and that the Dutch in Guiana call it *scare-sleep*. Dr. Hancock, however, states that the razor-grinder, or the *Aria Aria* of the natives, is a species of *Cicada*. In the typical genus *Fulgora* the head is dilated in front into the most remarkable projected protuberances, varying in each species, and which is the part of the body asserted by various writers to emit a strong light by night, analogous to that of the fire-flies.

Mr. Westwood alludes to this luminous property at some length. "Much uncertainty (he says) exists as to the real existence of any luminous power possessed by the typical species of this family. This account originated with Madame Merian (*Insecta Surinam*, p. 40.), who asserted it to be possessed by *Fulgora lateranaria* in an eminent degree, and her statement long received general assent, and appears to be the only authority for its existence. Olivier appears to be the first author who doubted the luminosity of the *Fulgore*, from information given to him by M. Richard, who had reared the *F. lateranaria* in Cayenne, and

had not found it to be luminous. Hoffman-segg, the Prince Von Nieuwied, and still more recently M. Lacordaire (the two last named authors having been long resident in South America), also concur in this opinion, none of the individuals they had ever seen alive exhibiting the least trace of

AMERICAN LANTERN-FLY
(FULGORARIA LATERALIS.)

luminosity. The majority of the natives also, who had been questioned on the subject, denied the luminous power, although a few affirmed it; hence Lacordaire suggests whether one sex may be luminous and the other not. Dr. Hancock read a memoir on the luminosity of the *Fulg. lateralis* before the Zoological Society, on 24th June, 1834, in which its luminosity is considered entirely fabulous. M. Westmael has recently reasserted the luminous property of the South American species, on the authority of a friend who had witnessed it alive. And W. Baird, Esq. has informed me of the existence of a Chinese edict, against young ladies keeping lantern-flies." Mr. Adam White, in the *Annals and Magazine of Natural History*, published an extract from a letter of J. Bowring, Esq. of Hong Chong, where the *F. Candelaria* is very abundant, but not known to be luminous. The species are generally very showy, and have been mostly figured by Mr. Westwood. In the British Museum there is a fine collection of them.

FULICA. [See COOT.]

FULMAR. (*Procellaria glacialis*.) A Palmiped bird belonging to the *Petrel* family; abounding in northern latitudes, though rarely seen in warm or temperate climates; in fact, it has been met with not only in arctic and antarctic regions, but even at the foot of those impenetrable barriers, the floating islands and eternal mountains of ice and snow. It measures seventeen inches in length, and weighs twenty-two ounces. The bill is about two inches long, and strongly formed; the hook or nail of the upper mandible, and the truncated termination or tip of the under one, are yellow; the other parts grayish; the nostrils are contained in one sheath, divided into two tubes. The head, neck, all the under parts, and the tail are white; back and wing-coverts blue gray; quills dusky blue; eggs yellowish, sometimes inclining to red. The body is thickly clothed with feathers upon a fine close down.

These birds are extremely greedy and gluttonous, and will devour any floating putrid substances: they feed principally on fish, and on the blubber or fat of whales, and other animals; which being soon convertible into oil, supplies it with provision for its young, and with the constant means of defence; for the Fulmar, like all the *Petrels*, has a peculiar faculty of spouting from its bill, to a considerable distance, a large quantity of pure oil. Pennant, speaking of those which inhabit the isle of St. Kilda, says—"No bird is of such use to the islanders as this: the Fulmar supplies them with oil for their lamps, down for their beds, a delicacy for their tables, a balm for their wounds, and a medicine for their distempers." The female is said to lay only one white and very brittle egg, which she hatches about the middle of June.

FUNGIA. A genus of Zoophytes, of which there are several species, both recent and fossil, principally from the Indian seas. They belong to the *Mudrephyllaea* of De Blainville, and consist of animals in nearly the lowest state of organization; for although they are universally allowed to be animals, they are completely without the power of motion, consisting simply of a living gelatinous film, which is endowed with the capability of constructing for itself a stony support or framework, derived from the surrounding water. In form it is generally orbicular or oval; mouth superior, transverse in a large disc, which is covered by many thick cirriform tentacula; and the disc is solidified internally by a calcareous solid *polymarium*, of a simple figure. We are indebted for the following interesting remarks to the elaborate description given of *Fungia* by Mr. Rymer Jones. "If we investigate the history of the *Fungia* a little more closely, it is beautiful to observe in apparently one of the most helpless and useless members of creation, the operations of the same power and foresight that shield and guard the highest and most intelligent. The *Fungia*, whilst it is alive, lies upon the sand at the bottom of the shallow seas of warm climates, or has its base loosely imbedded in the sand. It is unattached by any pedicle or root, so that a passing wave of any violence might easily take it up and

THICK-TENTACLED FUNGIA.
(FUNGIA CRASSENTACULA.)

wash it to a distance from the spot it originally occupied. This being the case, what

Is to prevent the wave from turning it upside down? It is only upon the upper surface that the living crust is spread, which forms the Fungia, so that should accident reverse its position the creature would inevitably perish. The arrangement adopted to prevent such an occurrence is simple enough, but not on that account less beautiful. The living film that coats its laminated surface has the faculty of secreting little bubbles of air within its substance; the bubbles so produced, although disseminated as it were at random, are sufficiently buoyant to act as floats, and thus provided, let the wave wash it ever so far, still the lightest side keeps uppermost, the floats prevent it from being reversed, and the creature settles down in a right position upon the smooth bottom of the sea." We may mention that our figure of the thick-tentacled Fungia (*F. crassitentaculata*) is derived from one of the French Voyages of Discovery, and shows the animals projecting from their coral home. The collection of corals and zoophytes in the British Museum, now most wondrously increased, contains many fine specimens of this very beautiful and distinct genus. As an ornament on a mantelpiece or on a table, under a bell glass, nothing perhaps is so pleasing as a fine and symmetrical specimen of this coral.

GADFLY. (*Estrus bovis*.) The Gadfly, or Ox Gadfly, is a Dipterous insect, about the size of a common Bee, with pale brown wings: it is of a pale yellowish brown colour, with the thorax marked by four longitudinal dusky streaks, and the abdomen by a black bar across it, the tip being covered with orange-coloured hairs. The genus is remarkable for its larvæ residing beneath the skin, or in different parts of the bodies of quadrupeds. When the female of this species is ready to deposit her eggs (which chiefly happens in August or December), she fastens on the back of a heifer or cow, and piercing the skin with the tube situated at the top of the abdomen, deposits an egg in the puncture; an operation which she repeats on many parts of the animal's back. Here the several eggs hatch, and the larvæ by their motion and suction cause so many small swellings or abscesses beneath the skin, which growing gradually larger, exhibit tubercles of an inch or more in diameter, with an opening at the top of each, through which may be observed the larva (a whitish oval maggot, which in time becomes brown) imbedded in a purulent fluid. There the larvæ remain till the middle of the next summer, when they force themselves out from their respective cells, and, falling to the ground, each creeps beneath the first convenient shelter, and lying in an inert state becomes contracted into an oval form, but without casting the larva skin, which dries and hardens round it. Having remained in the chrysalis state more than a month, it forces open the top of its coat, or pupa armour, and emerges in its perfect form. [Mr. Bracy Clark, F.L.S., has paid particular attention to the study of the family *Estridae*: we refer our readers for

further information to the articles BREEZE-FLY: (ESTRUS).]

GADUS: GADIDÆ The *Gadidæ*, or Cod tribe, are a family of Fishes belonging to the Malacopterygious (or soft-finned) order. They include the Cod, Haddock, Whiting, Ling, and others; and are distinguished by the following characters:—a smooth, oblong body, covered with small, soft, deciduous scales; head scaleless; eyes lateral; jaws and anterior part of the vomer furnished with several ranges of unequal, pointed teeth; the gills large, seven-rayed, and opening laterally; and a small beard or cirri at the tip of the lower jaw. Almost all the species have two or three dorsal fins, one or two anal, and one distinct caudal fin; and they have a large, strong, swimming-bladder, frequently dentated or lobed at its borders. They live for the most part in the seas of cold or temperate climates; and from their size and their tendency to congregate in particular localities, as well as from the wholesomeness and good flavour of their flesh, they are of first-rate importance to man. [See Cod, &c.]

GALAGO. (*Galago or Otolicnus*.) A genus of small quadrumanous animals, inhabiting different parts of Africa, and subsisting chiefly on insect food. They have great eyes; large membranous ears, which double down when at rest; hind limbs of a disproportionate length; and a long and tufted tail. The

SENEGAL GALAGO.—(*GALAGUS SENEGALENSIS*)

best known species are the GREAT GALAGO (*Galago crassicaudatus*), which is as large as a Rabbit; and the SENEGAL GALAGO (*Galago Senegalensis*), or gum animal of Senegal, the size of a Rat. "These pretty animals have at night all the activity of birds, hopping from bough to bough on their hind limbs only. They watch the insects sitting among the leaves, listen to the fluttering of the moth as it darts through the air, lie in wait for it, and spring with the rapidity of an arrow, seldom missing their prize, which is caught by the hands. They make nests in the branches of trees, and cover a bed with grass and leaves for their little ones. They are a favourite article of food in Senegal."

GALATHEA. A genus of long-tailed Crustacea. In the British seas four species are recorded as native: their porcelain texture, their sculptured carapace and wide tail, joined to their pleasing colours, especially when alive, render them very at-

tractive. Close to this genus is *Grimothea*, one of the species of which (*G. gregaria*) is met with in the Southern seas near the Straits of Magellan, in countless multitudes.

GALECINUS. [See SUPPLEMENT.]

GALEOPITHECUS. An extraordinary quadrumanous animal of the Lemurine tribe, called the *Flying Lemur*, and sometimes termed the *Coluga*; it is a native of the islands of the Indian Archipelago; and its chief peculiarity consists in the extension of its skin between the anterior and posterior limbs on each side, and between the posterior limbs, including also the tail; by which it receives

FLYING LEMUR AND YOUNG
(GALEOPITHECUS VOLANS).
WITH THE FRONT PART OF THE SKULL

a parachute-like support in the air, and is enabled to take long sweeping leaps from tree to tree, somewhat like flying. They may be considered as connecting the Lemurs with the Bats; differing generically from the latter in having their fingers, which are armed with trenchant nails, no longer than the toes, so that the membrane which occupies their intervals, and extends to the sides of the tail, can only answer the purpose of floating in the air. The general anatomy agrees very closely with that of the Lemurs. They inhabit lofty trees in dark woods; to which they cling with all four extremities, and traverse easily by means of their claws. During the day-time they suspend themselves like Bats from the branches, with the head downwards; but at night they rouse themselves, and make an active search for food, which consists of fruit, insects, eggs, birds, &c. They are very inoffensive; and generally produce two young at a birth.

GALERUCIDÆ. A group of leaf-eating beetles, separated from the *Chrysomelidæ* family, and consisting mostly of dull-coloured beetles: having an oblong oval, slightly convex body; a short and rather narrow thorax; slender antennæ, more than half the length of the body, and implanted close together on the forehead; slender legs, and claws split at the end. They fly mostly by day, and are either very timid or very cum-

ning, for, when we attempt to take hold of them, they draw up their legs, and fall to the ground. They sometimes do great injury to plants, eating large holes in the leaves, or consuming entirely those that are young and tender. The larvæ are rather short cylindrical grubs, generally of a blackish colour, and are provided with six legs. They live and feed together in swarms, and sometimes appear in very great numbers on the leaves of plants, committing ravages, at these times, as extensive as those of the most destructive caterpillars.

The *Galeruca vittata*, or striped Cucumber Beetle, a North American species recorded by Dr. Harris in his "Insects of Massachusetts," is of a light yellow colour above, with a black head, and a broad black stripe on each wing-cover, the inner edge of which is also black, forming a third narrower stripe down the middle of the back; the abdomen, the greater part of the fore-legs, and the knees and feet of the other legs, are black. It is rather less than one-fifth of an inch long. Early in the spring it devours the tender leaves of various plants; and makes its appearance on cucumber, pumpkin, and melon vines, about the end of May or the beginning of June, or as soon as the leaves begin to expand; and as several broods are produced in the course of the summer, it may be found at various times on these plants, till the latter are destroyed by frost. The females lay their eggs in the ground, and the larvæ feed on the roots of plants. Various means have been suggested to prevent the ravages of these striped cucumber beetles; as, wetting the vines with tobacco water, or with infusions of elder, walnut-leaves, or of hops; others recommend the use of soot, sulphur, Scotch snuff, or pepper, to be sifted upon the plants. In this country several species are found, which will be seen referred to in the works of Messrs. Stephens and Curtis.

GALICTIS. A genus of Carnivorous animals allied to the Civets and Genets.

GALLINÆ. The name given to an extensive order of Birds, including all those which constitute what are commonly termed "poultry," and furnishing us with the greater number of our farm-yard fowls, and with much excellent game. The name *Gallinæ* is applied to them from their affinity to the Domestic Cock, in common with which they have generally the upper mandible vaulted, the nostrils pierced in a large membranous space at the base of the beak, and covered by a cartilaginous scale. Their wings are short, their carriage heavy, and their flight laborious. They have an extremely muscular gizzard, and generally a large globular crop. In general they lay and incubate on the ground, on a few carelessly arranged stems of straw or grass. Some species are polygamous, and some monogamous; in the former the male is always larger and more gaily coloured than the female; in the latter the sexes nearly or quite resemble both in size and colour.

GALLINACEÆ. Some of the most

valuable birds we have belong to this order; Peacocks, Turkeys, Fowls, Pheasants, Partridges, &c. being of the number. Their bodies, for the most part, are large and muscular; their wings short; and their toes rough beneath, to enable them to scratch the ground in search of worms, &c. Many feed on grain and seeds, whilst others feed on berries, but the greater portion subsist likewise on insects. They are mostly polygamous, building their rude nests, in retired situations, on the bare ground. The females of several species are extremely prolific, and continue to lay eggs nearly all the year; the young follow the parent mother as soon as hatched, and she continues to protect them till they are fully grown. Some are easily domesticated; others remain in a wild state; but the flesh of nearly all furnish a substantial and wholesome food, while their plumage serves for various domestic and ornamental purposes. In their proper alphabetical order the reader will find them severally described.

GALL-INSECT. (*Gallinsecta*.) A family of insects, of a small size, which live upon trees or plants of various kinds. In the larva state they have the appearance of oval or round scales, closely attached to the plant or bark of the tree they inhabit, and exhibit no distinct external organs. If observed in spring, their bodies are noticed gradually to increase in size, ending in their acquiring the appearance of a gall, being either spherical, kidney-shaped, boat-shaped, &c. The skin in some is entire and very smooth; in others it is incised, or offers traces of segments. It is in this state that the females are impregnated, shortly after which they deposit their eggs, of which the number is very great; these they deposit between the ventral surface of their bodies and a layer of a cottony secretion. Their bodies subsequently dry up and become a solid cocoon, which covers the eggs; others envelope their eggs in a very abundant cottony secretion, which equally defends them. Many of them have been long celebrated for the beautiful dyes they yield. A very curious Gall constructed by a Homopterous insect, of a genus allied to Aphis, has lately been imported from the East by Mr. Morson. This, which is principally composed of gallic acid and tannin, has been particularly described in a late number of the Pharmaceutical Journal. [See *Coccus*: *KERMES*.]

GALLINULE. (*Gallinula*.) A genus of birds which frequent fresh waters, swimming and diving about, or running on land with equal ease and swiftness. The common Gallinule (*Gallinula chloropus*), called also the WATER-HEN or MOOR-HEN, is about fourteen inches in length, from the tip of the beak to the end of the tail, and weighs from eleven to fourteen ounces. The bill is upwards of an inch long, of a greenish yellow at the tip, and reddish towards the base; whence a kind of horny or membranous substance shields the forehead as far as the eyes: this appendage to the bill is perfectly red in the breeding season; at other times it varies or fades into white. The head is small and

black, except a white spot under each eye: the irides red: all the upper parts of the plumage dark shining olive green, inclining to brown; under parts dark hoary lead gray: vent feathers black; those on the belly and the thighs tipped with dirty white: the long loose feathers on the sides, which hang over the upper part of the thighs, are black, streaked with white; the feathers just beneath the tail are white; and the legs are dusky green. The toes are very long, particularly the middle one; their under sides flat and broad, whereby it is enabled to swim; and, from this part of its conformation, it may be regarded as the bird which connects the web-footed aquatic fowl with the fin-toed. The body is long, and the legs placed far behind; its feathers thickly set, and bedded upon down. It lies concealed during the day among reeds and willows, by the sides of rivulets; it can run over the surface of such waters as are thickly covered with weeds, and it dives and hides itself with equal ease: It flirts up its tail when running, and flies with its legs hanging down. In the evenings, it creeps by the margins of the waters, among the roots of bushes and long loose herbage, in quest of its food, which consists of insects, small fishes, worms, aquatic plants, and seeds: it is also granivorous; and if killed in September or October, after having had the advantage of a neighbouring stubble, its flesh is very good.

The Gallinule, or Moor-hen, makes its nest of reeds and rushes, closely interwoven, choosing for it a very retired spot close by the brink of the water; and it is said the female never quits it without covering her eggs with the leaves of the surrounding herbage. The female lays from five to eight eggs, of a light yellowish brown, marked with rust-coloured spots. Soon after the young are hatched, they take to the water, and shift for themselves. They differ considerably from the adults till after their second autumnal moulting, having till then a much lighter plumage.

"One circumstance respecting this familiar bird," Mr. Gould observes, "appears to have escaped the notice of most ornithologists: we allude to the fact of the female being clothed in a dark and rich plumage, and having the base of the bill and the frontal shield of a bright crimson-red tipped with fine yellow; her superiority in these respects has caused her to be mistaken for the male, which, contrary to the general rule, is at all times clothed in a duller plumage, and has the upper surface more olive than in the female; the bill is also less richly tinted.

There are very few birds of this genus; and most of them inhabit Java; but they are not by any means remarkable.

GALLIWASP. (*Celestus occiduus*.) A reptile of the Saurian order. It is nearly two feet in length from the nose to the tip of the tail, which, like the body, is thick and strong, tapering pretty suddenly towards the tip: the limbs are short, and the animal's whole appearance is remarkably stout

and planap: the teeth are small in front, but as they approach the back part of the jaws they increase considerably in size. It is a native of the West India islands, and seems to be particularly common in Jamaica, where it is said to frequent woody and marshy districts. It is usually of a palish brown colour, clouded with spots and bands of deeper cast, but it is reported to change its colour occasionally to a lively golden yellow.

GALLOWAY. A peculiar breed of strong, active, middle-sized horses; so called from the county of Galloway, in Scotland, which was formerly noted for them. Tradition reports, that the stock originated from several Spanish stallions, which swam on shore from some ships wrecked on the coast, belonging to the famous Armada; and, propagating with the mares of the country, furnished the kingdom with their posterity.

GAMBET. (*Totanus*.) A genus of wading birds, allied to the *Scolopacidae*, and including numerous species. The **GREENSHANK GAMBET** (*Totanus Gtlotis*) is the largest European species, being nearly the size of the Godwit, with the beak comparatively stout, and a little recurved; ashy-brown above and on the sides, with the margins of the feathers punctated with brown, the croup and belly white, and tail rayed with narrow irregular bars of gray and white; the feet green: in summer the throat and breast are marked with dusky spots, which disappear after the breeding season. It breeds on the margins of lakes, which it mostly frequents; is very clamorous when on the wing; and in winter resorts to the sea-shore.—The **DUSKY GAMBET** (*Totanus fuscus*), another European species, but rare in Britain, is more delicately formed, with particularly slender beak and feet, and beautifully barred tail and coverts; it becomes entirely suffused on the under parts with fuliginous black in the spring.—A third, the **REDSHANK GAMBET** (*Totanus calidris*), is very abundant in this country, breeding also not uncommonly in marshes near the sea-shore, and especially about the estuaries of rivers.—There are others, as the delicate **WOOD GAMBET** (*Totanus glareola*), remarkable for the extraordinary length of its legs, and its habit of gracefully tripping across the broad floating leaves of aquatic plants when in search of its prey; and the **GREEN GAMBET**, (*Totanus ocloropus*), with shorter legs, and easily known as it flies by its conspicuous white rump.

GAME, BLACK and RED. [See Grouse.]

GAMMARUS: **GAMMARIDÆ.** A genus and family of Crustaceans belonging to the order *Amphipoda*. The body of this marine genus is covered with a coriaceous, elastic tegument, generally compressed and arched: the posterior extremity of the tail is not furnished with swimmerets, but its appendages are in the form of cylindrical or conical styles. Two at least of the four anterior legs are terminated by claws. The vesicular bags (the use of which has not been ascertained) are situated at the external

base of the legs, commencing with the second pair, and accompanied by a small plate. The pectoral scales enclosing the eggs are six in number. There are several species of this family found in the British seas; for an account of which we must refer our readers to the works of Milne Edwards and Kroyer, but especially of the latter. The genera *Talitrus*, *Orchestia*, *Dexamine*, *Amphithoe*, and others recorded in the List of Crustacea in the British Museum, belong to this family. The habits of some of these are very interesting. [See AMPHIPODA, &c.]

GANNET, or SOLAN GOOSE. (*Sula Bassana*.) This Palmipede bird is about the size of the tame goose; its length two feet nine inches, and its weight nearly seven pounds. The bill is six inches long, jagged at the sides, and straight almost to the point, where it inclines downwards; a darkish line passes from the brow over the eyes, which are surrounded with a naked blue skin, and, like those of the Owl, are set in the head so as to look nearly straight forward, and the extreme paleness of the irides gives them a keen wild stare. A loose black bare skin,

COMMON GANNET. — (*SOLA BASSANA*.)

capable of great distension, hung from the blades of the under bill, and extended over the throat, serves it as a pouch to carry provisions in the breeding season to its mate and young. The neck is long; the body flat, and very full of feathers; the crown of the head, and a small space on the hind part of the neck, are buff-coloured; and, with the exception of the quill and bastard-wing feathers, the rest of the plumage is white. The legs and toes are black; but the fore part of both are marked with a pea-green stripe; and the tail is composed of twelve tapering sharp-pointed feathers, the middle ones being the longest. The male and female are nearly alike; but the young birds, during the first year, are of a dusky hue, speckled with numerous triangular white spots; and it is not until the third year that the plumage is perfected.

In the Hebrides, the north of Scotland, and in Norway, this species is very abundant; it is also met with in great numbers on the coasts of Newfoundland and other northern regions, as well as in more temperate climates of both hemispheres. Their food consists chiefly of salt-water fish, the

herring and pilchard being their favourites; and they take their prey by darting down upon it from a considerable height. They make their nests, which are composed chiefly of turf and sea-weeds, in the caverns and fissures of rocks, or on their ledges, as well as on the plain surface of the ground. The female (according to Bewick) lays three white eggs, somewhat smaller than those of a goose; but we find it elsewhere stated, that the Gannet, if not disturbed, will lay only one egg throughout the year; but if that be taken away, it will lay another, and in like manner a third, which she is generally permitted to hatch. Their greatest known rendezvous is the Hebrides and other solitary rocky isles of North Britain, such as the Bass in the Firth of Forth, and Ailsa Crag, in the Firth of Clyde, where their nests, in the months of May and June, are described as so closely placed together, that it is difficult to walk without treading upon some of them; and it is said that the swarms of the old birds are so prodigious, that when they rise into the air, they stun the ear with their noise, and overshadow the ground like the clouds. The inhabitants of the islands where these birds breed derive considerable emolument from the produce of their eggs; but to obtain them they encounter the most fearful risks, now climbing rocks which are almost inaccessible, and now clinging to the craggy precipices which, at a prodigious height, overhang a raging sea.

In Mr. Couch's "Cornish Fauna" we are told that "the Gannet takes its prey in a different manner from any other of our aquatic birds; for, traversing the air in all directions, with a heavy and irregular flight, as soon as it discovers the fish it rises to such a height as experience shows best calculated to carry it by a downward motion to the required depth, and then partially closing its wings it falls perpendicularly on the prey, and rarely without success, the time between the plunge and emersion being about fifteen seconds. When pilchards are collected into a narrow space, the number and eagerness of the Gannets are such, that it is surprising they do not fall on and kill each other. Their clamour indeed at such times proves them to be well on their guard, but it is also probable that every one in falling has its eye fixed on the fish it intends to seize, and the well-polished wings direct it unerringly to its prey. The form and setting on of the Gannet's wings well fit it for assuming the perpendicular attitude preparatory to its fall, which is effected with ease, rapidity, and precision. They are attached to the body about the centre of gravity, so that the anterior parts drop as on a pivot, and the elbow being about the middle of the distance between the shoulder and wrist, a slight inclination in any direction is sufficient to regulate the motion." There are also other species bearing the name of Gannet, but the one just described is the best known and the largest. The *White Gannet*, which inhabits China: the *Booby Gannet*, common on the coasts of South America, and described as being a very stupid bird; hence the appellation given to it by sailors:

and the *Brown Gannet*, belonging to the West Indies and the western coast of tropical Africa. [See *SULA*.]

GARFISH. (*Esoc belone*.) This fish has a variety of names; as, Garfish, Sea-pike, Sword-fish, Greenbone, Mackerel-Guide, Sea-Needle, &c. It generally precedes the Mackerel in their annual visit to shallow water for the purpose of spawning, and is taken on various parts of the Dutch, English,

GAR-FISH. — (*ESOC BELONE*.)

Scotch, and Irish coasts. It is from twenty to twenty-four inches in length, with long, narrow, beak-like snout, the under jaw projecting; the teeth are numerous and minute, the eyes large; the dorsal and anal fins opposite each other; pectoral and ventral fins small; and the tail considerably forked. The upper part of the head and back is of a dark green hue, the sides paler, and the belly a silvery white. It is a very voracious fish, and seizes the bait with avidity. The flesh of the Garfish has somewhat the flavour of Mackerel, but is more dry; and the bones are green.

GARROT. (*Clangula*.) A genus of the Duck family, widely distributed over the colder and temperate regions of both Europe and America. The head is large, compressed, rounded above; bill shorter than the head, higher than broad at the base; neck short and thick; body ovate and depressed; eyes small; legs very short, and placed far behind; hind toe lobed. They breed in the colder regions of Europe and America, returning to more temperate climes in winter. They haunt rivers, lakes, estuaries, and feed chiefly on molluscs, and also on larvæ, crustacea, and sometimes small fish, for which they dive. 1. The *GOLDEN-EYED GARROT* (*Clangula vulgaris*) is a common species in Britain; 2. The *HANLEQUIN GARROT* (*Clangula histrionica*) occurs as a rare straggler. [See *DUCK*.]

GASTEROPODA. The name of a class of molluscous animals which move from place to place by means of a fleshy disc, or foot, situated under the abdomen. The greater part of these Mollusca consist of animals inhabiting a univalve shell, which is cone-shaped and rolled into a spiral; and of such the snail is a familiar specimen. Some species, on the contrary, have no shell; of which the slug is an example. The body is elongated, and terminates in front by a head, more or less developed, with a mouth provided with from two to six tentacula; the back is enveloped in a mantle, which secretes the shell; and the belly is covered on its under side by the fleshy mass of the foot. In most aquatic Gasteropods whose shell is spiral, there is a horny or calcareous disc, called the *operculum*, which is attached to the hinder part of the foot, and is used for closing the entrance of the shell when the animal withdraws itself. Some of the Gas-

teropoda inhabit fresh waters, but most of them are marine animals: some are formed for crawling, as the snail, the whelk, &c.; some are more adapted for swimming; while a few of this class attach themselves to the surface of rocks, scarcely varying their locality, as is the case with the limpet; this attachment being produced by the adhesion of the muscular disc, or foot, which acts like a sucker, and can at any time be detached by the will of the animal.

In the work of Mrs. Gray, of the British Museum, on Mollusca, are figures of the animals of most of the genera of Gastropoda. To this very carefully executed and authoritative work, we refer our readers, as well as to the various miscellaneous articles in this work; such as *ACHATINA*, *BULIMUS*, *SNAIL*, &c.

Fossil Gastropoda. Among the numerous organic remains which exist, none are more extensively diffused throughout the globe, occupying the various geological formations, than fossil univalve shells. It is, indeed, asserted by some of the most experienced geologists, that every fossil turritinated univalve of the older beds, from the transition lime to the lias, belongs to the hercynian genera, which class extends through every stratum in the entire series of geological formations, and still retains its place among the inhabitants of our existing seas: while, on the other hand, the shells of marine carnivorous univalves are very abundant in the tertiary strata above the chalk, but are rare in the secondary strata from the chalk downwards to the inferioroolite; beneath which no trace of them has yet been found.

GASTEROSTEUS. [See *STICKLEBACK*.]

GASTORNIS. [See *SUTTLENT*.]

GASTROBRANCHUS. (*Gastrobranchus glutinosus*). The *LAGO*, A cartilaginous fish, which in its general appearance bears a near resemblance to the Lampreys, but which in the *Systema Naturæ* of Linnæus has been considered as belonging to the class *Vermes*. It is of a dusky bluish cast above, and reddish towards the head and tail; is from four to six inches long, and is remarkable for its total want of eyes: the mouth, which is situated beneath, is of an oblong form: on each side are two beards or cirri, and on the upper part four; in front of the top of the head is a small spout-hole, furnished with a valve, by which it can at pleasure be closed: the teeth, which are of an orange-colour, are arranged on each side of the mouth in a double-row, and in the middle of the roof of the mouth is one sharp-pointed and curved tooth. It has no scales, nor any kind of fin but that which forms the tail, the extremity of the body, where it is surrounded by the caudal fin, which is very shallow, being pointed. Beneath the body, from head to tail, runs a double row of equi-distant pores, through which, on pressure, exudes a viscid fluid; and beneath the body are two spiracles having apertures communicating with a series of six globular red cells or vesicles on each side of the body. "The manners of this fish are represented as highly singular:

it is said to enter into the bodies of such fishes as it happens to find on the fishermen's hooks, and which consequently have not the power of escaping its attack, and by gnawing its way through the skin, to devour all the internal parts, leaving only the bones and the skin remaining. Another peculiarity in this animal consists in its uncommonly glutinous nature: if put into a large vessel of sea-water it is said in a very short space to render the whole so glutinous as easily to be drawn out into the form of threads. When taken out of water the *Gastrobranchus* is said to be incapable of living more than three or four hours." The species we have been describing is called the *Blind Gastrobranchus*, and is an inhabitant of the Northern seas. Another, and a much larger one, called the *Dombeyan Gastrobranchus*, from its having been first noticed by M. Dombey, is found in the South American seas.

GASTROCHÆNA. The name given to a genus of Acephalous Molluscs, found on the coasts of Great Britain and America. They inhabit an equivale, inequilateral shell, united by a ligament, and having in the interior a small spoon-shaped curvature. The *Gastrochæna* penetrates and makes its abode in hard substances; and seldom exceeds half an inch in length. They are found in the hollows of shells or other marine substances.

GAVAL, or GARIAL. An enormous Reptile found in India, to which the name of the *GANGETIC CROCODILE* (*Crocodilus Gangeticus*) is sometimes applied; but the sub-genus termed *Garial*, by Cuvier, is so strikingly distinguished both from the *Crocodile* of the Nile and the *Alligator* by the peculiar form of the mouth, that it is hardly possible, even on a cursory view, to confound it with either of them; the jaws being remarkably long, narrow, and straight, constituting the anterior part or beak, spreading out at its base, and terminating in front, so as to remind the observer of the beak of the Spoonbill. The head, properly so called, has its sides straight and perpendicular, the upper surface being quadrilateral; and the mandible, instead of being continued from the forehead by a gradual slope, sinks suddenly to follow a straight and nearly horizontal direction. In the general form and colour of the body and limbs it resembles the common *Crocodile*, but the number of transverse zones or bands formed by the rows of scales on the back, is greater than in that species. The teeth are nearly double the number of those of the *Nilotic Crocodile*, and are of equal size throughout the whole length of the jaws. It is quite as aquatic in its habits as is the African species; its hind feet fully webbed; and the crest on the tail, increasing the surface by which it strikes the water, is much elevated. This powerful animal frequently attains the length of twenty-five feet; and, from its strength and ferocity, is truly formidable. In one respect, however, it is found very serviceable, viz. in devouring the numerous dead bodies of men and animals which are committed to the "sacred river," the effluvia arising from which would other-

wise, in all probability, be productive of contagious diseases. Analogous species of Crocodiles have been found in a fossil state in Yorkshire and other places. The fossil group is named *Teleosaurus* [which see].

GAZELLE. (*Antelope Dorcas.*) Of all the Antelopes of the East none are so celebrated for beauty as the Gazelle; and oriental poets, from time immemorial, have thought that the highest compliment they could pay the female sex was to compare the eyes of a lovely woman with the lustrous organs of vision which distinguish that light and graceful animal. This very beautiful species inhabits Arabia and Syria, where they are seen in large groups, bounding across the desert with such amazing fleetness that they seem, bird-like, to skim over the surface. It is so swift that the greyhound is generally unable to overtake it without the assistance of falcons, which fly at its head and thus check its speed till the

GAZELLE. — (ANTILOPE DORCAS.)

dogs regain their lost distance. The Ariel Gazelle is about twenty inches high at the shoulder; its limbs are slender, but vigorous; and all its actions are spirited and graceful. It is of a dark fawn colour above, and white below; the upper parts being divided from the lower by a deep dark band along the flanks. On each side of the face a broad stripe of white passes from the horns over the eyes to the nose. Wild and timid as the Gazelle is, when taken young it is readily domesticated; and it is frequently seen at large in the court-yards of houses in Syria, their exquisite form, general beauty, and playfulness rendering them especial favourites.

GECARCINUS. The name given to those Crustaceans which are formed to live at a distance from the sea; some residing in fresh water, and some burrowing in the ground, even at a distance from water. [See *Land Crab*, art. *CRAB*.]

GECKO. This name is given to a considerable number of Saurian Reptiles, and is said to be taken from the sound of their voice, which resembles the word *gecko* uttered in a shrill tone. Our figure, which represents a common New Holland species, is named by Mr. Gray *White's Phyllurus*, or

Gecko. It was first described by Dr. Shaw in White's Voyage to New South Wales, and is the *Phyllurus platurus* of naturalists; but though very characteristic of the group we prefer giving an account of the **COMMON GECKO** (*Gecko versus*): — It is of a thicker and

WHITE'S GECKO. — (PHYLLURUS PLATURUS.)

stouter form than most other lizards, having a large and somewhat triangular flattish head, covered with small scales, a wide mouth, large eyes, minute teeth, and a broad flat tongue. The limbs are of moderate length, and the feet are of a broader form than in the rest of the genus *Lacerta*, each toe being dilated on the margins, and divided beneath into a great number of parallel transverse lamellae, without any longitudinal mark or furrow; all the toes, except the thumbs, are furnished with small claws; the tail, which is generally longer than the body, is marked, more or less, according to the age, into divisions or verticillated rings: the whole animal is covered on the upper parts with numerous, distant, round warts or prominences, approaching more or less to an acute form in different individuals, and sometimes obtuse: beneath each thigh is a row of perforated papillae, as in the Green Lizard and many others: the under parts of the body are covered with scales of somewhat dissimilar appearance, but all approaching to a round figure."

In describing the habits, food, &c. of the *Geckotidae*, Mr. Brodrip observes that "the greatest number feed on small animals, such as insects, their larvae and pupae. These they catch either by lying in ambush, or by pursuing their feeble prey in the holes and dark crevices to which it retires. The structure of their feet enables them to run in every direction over the smoothest surfaces, and they can even remain suspended beneath the large leaves which a luxuriant tropical vegetation so frequently puts forth. The sharp and retractile nails with which the feet of the greater number are armed enable them to cling to and make rapid progress on trees with the smoothest bark, or penetrate

the holes of rocks, and to climb walls. Of sombre or varying colours adapted generally to the locality where their lot is cast, they will often remain for hours in positions as extraordinary as the flies and insects for which they watch, the wonderful apparatus with which their feet is furnished enabling them to overcome the general law of gravity, and without which they would instantly fall to the earth. The hues of their skins thus render them less objects of suspicion to the little animals for which they lie in wait, and also serve to dodge even the acute eye of the bird of prey that seeks to destroy them. Their eyes enable them to discern objects in the dark, and are at the same time capable of bearing the rays of a bright sun; for many insects are nocturnal or crepuscular, while the great mass of them are diurnal. The pursuit of their prey leads them near the habitations of man, whose dwelling always attracts certain kinds of insects, and they sometimes fall victims to their appearance, which frequently inspires terror, and often disgust. A Gecko, confident in his powers of flight, appears boldly to await his adversary, and his sudden disappearance at a nearer approach adds to the horror which his uncouth form inspires. The poor Geckos too have a bad name. They are supposed to poison whatsoever they touch, be it animate or inanimate, and their saliva is said to vex the skin of those on whom it falls with foul eruptions. Many of these cuticular irritations, when they have actually existed from the intervention of these animals, may have arisen from the extremely sharp claws of a Gecko running over a sleeping man, or small blisters may have been raised by the adherent apparatus at the bottom of its feet. In each great division of the globe various species of the Geckotidæ are found, though very few of them exist in Europe.

Descriptions of the numerous species will be found in Mr. Gray's catalogue of the reptiles in the British Museum, where there is a large collection of these interesting lizards. By some biblical commentators, "the spider that taketh hold with her hands, and is in king's palaces" is believed to have been a Gecko; Geckos are very common in houses in the East, and may be seen running about the walls.

GENET. (*Viverra genetia*.) This animal belongs to the Weasel tribe; has a very beautiful soft fur; and is about the size of a very small cat, but is of a longer form, with a sharp pointed snout, upright ears, slightly pointed, and very long tail. The colour of the Genet is usually a pale reddish grey, the sides of the body being spotted with black, and a dark line running along the back; where the hair, being longer than on the other parts, resembles a slight mane: the muzzle is dusky; beneath each eye is a white spot; the cheeks, sides of the neck, and the limbs, are spotted in a proportionally smaller pattern than the body, and the tail is marked with black and white rings. Easily tamed, and of a mild disposition, the Genet, at Constantinople, and various other

parts of the East, is domesticated like the Cat, and is said to be equally if not more serviceable in clearing houses of rats and other vermin. It is a native of the western parts of Asia, and is also occasionally found in Spain; but though it requires a warm climate for its subsistence and propagation, it has not been discovered in India or any part of Africa. This animal, like the Civet, produces an agreeable perfume; it is, however, less powerful, and its scent much sooner evaporates.

There are two or three other species found in the East; among these may be mentioned

RASSE GENET.—(*VIVERRA MALACCENSIS*.)

the Rasse (*Viverra Malaccensis*), found in Java by Dr. Horsfield, but also a native of the Indian continent: our figure shows this well-marked species.

GEOMETRIDÆ. A family of Lepidopterous insects, of very considerable extent. It is distinguished from the NOCTUIDÆ by its general weakness of structure and slenderness of body, but still more by the remarkable peculiarities and mode of progression of the caterpillars. The wings are large and of various outlines; in general they are horizontally extended, but in a few species they are carried vertically; the maxillæ short, weak, and nearly membranous; the labial palpi small and cylindrical; the antennæ variable, being in some males strongly bipectinated; the legs are slender, the anterior tibiae being armed with a spur on the inside, and the posterior with two pairs. From their peculiar mode of progression, the caterpillars are called *Loopers* or *Geometricians*: they have only three pairs of pectoral, and one pair of ventral pro-legs, with a pair of anal feet; they then extend the body to its greatest length, when they put down their fore feet, drawing the hind part of the body as close after them as possible, so as to form an arch, like a pair of compasses, fixing their hind feet, and proceeding again as before. It is evident that they possess great muscular power, and hence their positions during repose are very striking. Fixing themselves by their anal feet alone, they extend their bodies in a straight line, holding it in that position for a long time together. This, together with their obscure colours, and the warts on their bodies, renders it often quite difficult to distinguish them from twigs of trees on which they feed. When alarmed, these caterpillars have the instinct to drop from the leaves, and suspend themselves by a thread, which enables them to remount when the danger is past. The

chrysalides are sometimes naked and suspended by the tail, but more frequently enveloped in a slight cocoon, and placed among dry leaves, &c. In their perfect state the Geometridæ fly singly in the twilight, or, if abroad in the day, and are disturbed, they quickly settle again amongst the foliage. Many species have a broad wavy band across the fore wings; these are called Carpet Moths. Figures of all the British species will be found in the very useful work of Mr. Humphreys, "The British Moths."

GEOPHAPS. A genus of birds found in Australia, belonging to a minor group of the *Columbidae* family, whose habits and economy are very peculiar. Several species are described by Mr. Gould, from whose superb work we glean the following particulars of one, named—

GEOPHAPS SCRIPTA, or PARTRIDGE BRONZE-WING. This bird is said to be second to none in the world as a delicate viand for the table; while it is equally interesting to the sportsman, no other bird not strictly gallinaceous so closely resembling the genus *Perdix* (Partridges) in many of its habits and manners; in Mr. Gould's opinion, indeed, "in no instance is the theory of the analogical relationship of one group to another more strikingly borne out than in the close resemblance of the members of this group to those of the genus *Perdix*." It is sometimes seen in pairs, but more frequently in small coveys of from four to six in number, which, when approached, generally run off with exceeding rapidity, and crouch down among any scanty herbage, instead of seeking safety by flight; the colouring of the bird assimilating so closely to that of the ground or the herbage, that when crouched down for shelter it is not easily to be seen. When it rises, it does so with great rapidity, making a loud whirring noise with its wings, and generally alighting on the horizontal branch of a large tree. On such plains as are intersected with rivers and pools of water, the Partridge Bronze-wing is mostly found; and its principal food is the seeds of various grasses and other small plants, to which are occasionally added insects and berries. The plumage of the head, back, and chest is light, the edges of the primaries and the extremities of the wing-coverts being much paler; a broad stripe of white runs from beneath the mandible to beneath the eye, another stripe from the posterior angle of the eye down the side of the neck, the interspaces being jet black, which colour surrounds the eye, and also forms a crescent across the lower part of the throat; abdomen gray; flanks white; tail grayish brown, tipped with black; naked skin round the eye bluish lead-colour; bill black; feet dark purplish brown. The female lays two eggs on the bare ground, without any nest; and the young birds run and fly strongly when they are only as large as a quail.

GEOPHILUS. [See CENTIPEDE.]

GEOSPIZA. A genus of the Finch tribe, found by Mr. Darwin on the Galapagos Islands, and characterised by the species

having an enormously thick and well-developed hard bill. They are terrestrial in their habits. The accompanying cut, copied

THICK-BILLED GROUND-FINCH
(*GEOSPIZA MAGNIROSTRIS*.)

from Mr. Gould's figure in the Bird portion of the zoology of the voyage of H.M.S. Beagle, will show the form and appearance of the *GEOSPIZA MAGNIROSTRIS*, and the accompanying extract from the ever-interesting journal of Mr. Darwin tells us all that is known of their habits. "These birds," he says, "are the most singular of any in the Galapagos archipelago. They all agree in many points, namely, in a peculiar structure of their bill, short tails, general form, and in their plumage. The females are gray or brown, but the old cocks jet-black. All the species, excepting two, feed in flocks on the ground, and have very similar habits. It is very remarkable that a nearly perfect gradation of structure in this one group can be traced in the form of the beak, from one exceeding in dimensions that of the largest grosbeak, to another differing but little from that of a warbler."

GERBILLUS. A genus of Glires mammalia, chiefly found in South Africa and in India: most of the species are long-tailed, and may be seen in the British Museum collection.

GERBOA. (*Dipus Egyptus*.) [See JERBOA.]

GHOST-MOTH. (*Hepiolum humuli*.) A nocturnal Lepidopterous insect, which receives this name from the male being of a white colour, and from its habit of hovering with a pendulum-like motion over one spot (often in church-yards), where the female is concealed. Of the singular habits of this insect the following interesting particulars are set forth in the "Journal of a Naturalist." The larva which produces this creature is hidden in the ground during the season of winter; the fly being formed in the month of May, and soon rising from the soil, then commences its short career. At this time one or more of them may frequently be observed under some hedge in a meadow, or some low place in damp pasture, only a few feet from the ground, persevering for a length of time together in a very irregular flight, and falling, and balancing about in a space not exceeding a few yards in circumference, an action not observable in any other, and fully indicating this moth. This procedure is not

the meaningless vagary of the hour, but a frolicsome dance, the wooing of its mate,

LARVA AND CHRYSALIS OF GHOST-MOTH.

which lies concealed in the herbage over which it sports. The two insects are something similar in their general form, but very differently marked. The male exhibitor is known by his four glossy, satiny, white wings, bordered with buff; the lady reposer

MALE GHOST-MOTH.
(HEPIOLUS HUMULI.)

has her upper wings of a tawny yellow, spotted and banded with deep brown. They are very inert creatures, easily captured; and their existence appears to be of very short duration, as we soon cease to observe them, either in action or at rest. The male probably becomes the prey of every bird that feeds by night; his colour and his actions rendering him particularly obnoxious to dangers of this nature; and the frequency with which we find his wings scattered about, points out the cause of death to most of them. The bat pursues with great avidity all those

FEMALE GHOST-MOTH.
(HEPIOLUS HUMULI.)

creatures that fly in the evening; and by its actions it seems to meet with constant employment, and has greater probability of success than some insectivorous birds that feed by day, as all the myriads which abound at this time are the sole prey of itself and a few nocturnal rambles. From this singular

sight in the twilight hour, haunting as it were one particular spot, the fancy of some collector, considering it as a spectre-like action, named it the Ghost-moth.

GIBBON. (*Pithecus lar.*) The Gibbon, or Long-armed Ape, is a species of the *Quadrumanus*, distinguished from others by the slenderness of its form, but more particularly by the extraordinary length of its arms, which, when the animal is standing erect, reach to the ankle-joints. The hands and feet are even more adapted for climbing than those of the Orang-Outang; their form, in fact, is admirably suited to their arboreal habits; and they are here observed to sweep from the branch of one tree to another with surpassing velocity: suspending themselves by their long anterior limbs, they launch onwards by an energetic muscular movement, seizing with wonderful precision the distant branches, and continuing their progression without any pause or perceptible effort. It is worthy of note, that their feet, which are very long, have the soles turned so much inwards as to afford no support to the erect posture. The colour of the Gibbon is black; but the face is commonly surrounded with a white or grey beard. There is a variety, called the WHITE GIBBON, which

GIBBON, OR LONG-ARMED APE.
(PITHECUS LAR.)

differs from the above species in being entirely white, except the face and hands, which are black.—Notwithstanding the apparent ferocity of the Gibbon, and its ungainly figure, it is of a more gentle and tractable nature than any of its congeners; and it has even been commended for the decorum and decency of its behaviour. It inhabits the islands of the Indian Archipelago.

GILTHEAD. (*Chrysophrys auratus.*) An Acanthopterygious fish, of a broad and compressed form, about twelve inches in length, and somewhat resembling the Bream. It is found in abundance in the Mediterranean, and is sometimes taken on the coasts of France and Spain. The hack is sharp, and of a dusky green or silvery gray colour; between the eyes there is a gold-coloured crescent-shaped stripe, from which it receives its name: the incisor teeth in each jaw are conical, the molar ones roundish; the tail is very forked, the fins are grayish-blue, the dorsal fin extending almost the

whole length of the back. It feeds on various kinds of crustacea and mollusca; and chiefly inhabits deep waters and bold rocky shores.

GIRAFFE, or CAMELOPARD. (*Camelopardalis Giraffa*.) This most remarkable Ruminant, which in its general structure most nearly approaches the Deer, has points of affinity, also, with the Antelopes and Camels, besides very striking peculiarities of its own. If height alone constituted precedence among quadrupeds, the Giraffe, as *Le Vailant* justly observes, must hold the first rank. The enormous apparent length of the fore legs and its long tapering neck must strike every one at the first glance: while its small and elevated head, its large and brilliant eyes, its mild aspect, and the whole contour of the animal, differing from all others, cannot fail to excite admiration; for, notwithstanding the unusual proportions of the limbs, its general form is not merely elegant but highly picturesque. The horns of the Giraffe differ both in texture and shape from

SKULL OF GIRAFFE.

those of all other horned quadrupeds; forming, as it were, a part of the skull, and consisting of two porous bony substances, about three inches long, with which the top of the head is armed, and which are placed just above the ears, and crowned with a thick tuft of stiff upright hairs; a considerable protuberance also rises on the middle of the forehead between the eyes, which appears to be an enlargement of the bony substance, similar to the two horns just mentioned. The neck is furnished with a very short stiff mane. The tail is of moderate length, gradually tapering towards the end, and terminating in a tuft of long hair. The fore part of the body is very thick and muscular; the hind part thin and meagre. The Giraffe, in its wild state, when full grown, measures seventeen feet from the top of the head to the fore feet; the female, however, is not so high; and it must be understood that this measurement is taken at the maximum height, none of those brought to or bred in Europe having reached more than fourteen feet. At first view the fore legs seem twice the length of the hind: but this difference, on accurate examination, appears to result chiefly from the extraordinary height of the shoulders.

The colour of the Giraffe is a light fawn, marked with numerous large spots of a

darker hue, less regularly shaped on the sides than on the neck and shoulders. The vertebrae of the neck are slightly curved; but although nothing can exceed the gracefulness of form which this part sometimes presents, the firmness of the joints prevents the neck from being generally bent or arched with swan-like elegance. The peculiarities of conformation which this animal displays are all adapted to the mode of life which is natural to it; for it is destined to browse upon the foliage and young shoots of trees, at a height far greater than that which any other animal can reach, whilst standing on the ground. For this purpose it is furnished with an elongated prehensile tongue, with which it lays hold of the tender branches, and draws them into its mouth; being assisted by its projecting upper lip, which is at once flexible and very muscular. In order to bring its mouth to the ground, which it seldom does except to drink, or to pick up some unusual delicacy, the Giraffe is obliged to stretch its fore legs widely apart, and to bend its neck into a semicircular form. "The head of the Giraffe resembles that of the camel in the absence of a naked muzzle, and in the shape and organization of the nostrils, which are oblique and narrow apertures, defended by the hair which grows from their margins, and surrounded by cutaneous muscular fibres by which the animal can close them at will. This is a beautiful provision for the defence of the air passages, and the irritable membrane lining the olfactory cavities, against the fine particles of sand which the storms of the desert raise in almost suffocating clouds. The large, dark, and lustrous eyes of the Giraffe, which beam with a peculiarly mild but fearless expression, are so placed as to take in a wider range of the horizon than is subject to the vision of any other quadruped. While browsing on his favourite acacia, the Giraffe, by means of his laterally projecting orbits, can direct his sight so as to anticipate a threatened attack in the rear from the stealthy lion, or any other foe of the desert. To an open attack he sometimes makes a successful defence by striking out his powerful and well-armed feet; and the king of beasts is said to be frequently repelled and disabled by the wounds which the Giraffe has thus inflicted with his hoofs. The horns of the Giraffe, small as they are, and muffled with skin and hair, are by no means the insignificant weapons they have been supposed to be. We have seen them wielded by the males against each other with fearful and reckless force; and we know that they are the natural arms of the Giraffe most dreaded by the keeper of the present living Giraffes in the Zoological Gardens, because they are most commonly and suddenly put in use. The Giraffe does not butt by depressing and suddenly elevating the head, like the deer, ox, or sheep; but strikes the callous obtuse extremity of the horns against the object of his attack with a side-long sweep of the neck. One blow thus delivered at full swing against the head of an unlucky attendant would be fatal:—the female once drove her horns in sport through

an inch board. Notwithstanding those natural arms of hoofs and horns, the Giraffe does not turn to do battle except at the last extremity; where escape is possible, it seeks it in flight. This is extremely rapid, especially along rising ground; but cannot be maintained for a sufficient period of time to enable it to escape the Arah mounted on his long-winded steed. The paces of the Giraffe, owing to the disproportion between his long legs and short body, are very peculiar: when walking at a brisk rate, it seems to move forward simultaneously the two legs of the same side, as noticed of old by the learned bishop of Sicca, in his account of the presents brought to Hydaspes by the Abyssinian ambassadors." "In the sanded paddock appropriated to the Giraffes in the Zoological Gardens, they exhibit in the warm days of summer all their various and singular paces. In the simple walk, the neck, which is then stretched out in a line with the back, gives them a stiff and awkward appearance; but this is entirely lost when they commence their graceful undulating canter." "The tongue is an organ exquisitely formed for prehension; it is used to hook down the branches which grow beyond the reach of the muzzle of the Giraffe, and the animal in captivity instinctively puts it to use in a variety of ways. We have seen the Giraffe, in the Jardin des Plantes at Paris, stretching upwards its neck and head, and protruding its tongue to the full extent, to hook out single straws, which were platted into the partition, separating it from the contiguous inclosure. In our own menagerie at Regent's Park many a fair lady has been robbed of the artificial flowers which adorned her bonnet, by the nimble flicking tongue of the rare object of her admiration. The Giraffe seems, indeed, to be guided more by the eye than the nose in the selection of objects of food; and if we may judge of the apparent satisfaction with which the mock leaves and flowers so obtained are masticated, the tongue would seem by no means to enjoy the sensitive in the same degree as the motive powers. The difference in the size of the nerves of sensation and motion which we observed in the dissection of the tongue accords with these habits of the living animal. From the same dissection it was proved that the movements of the tongue, both those of extension, prehension, and retraction, were due to muscular, and not, as Sir Everard Home supposed, to vascular action. Observations of the living animal, and dissection of the dead, have at length dispelled most of the errors and doubts which obscured the exact knowledge of the nature and zoological affinities of the Giraffe."—"A Giraffe more than two-thirds grown will eat daily in confinement eighteen pounds of clover hay, and eighteen pounds of a mixed vegetable diet, consisting of carrots, mangel-wurzel, barley, split beans, and onions; and will drink four gallons of water. They copulate in March. The female has four inguinal udders: she brings forth one young at a birth; and the period of gestation is fifteen months. The new-born Giraffe measures six feet from the fore-hoofs

to the top of the head. In a few hours it is able to follow the dam. It resembles the mature animal in the markings of the hide. The first Giraffe known to have been produced in captivity was brought forth in June, 1839, at the gardens of the Zoological Society of London."—*Brande's Dict.* Two varieties of this curious animal are known; one of them peculiar to Nubia, Abyssinia, and the adjacent districts; the other a native of Southern Africa.

The remains of an animal closely allied to the Giraffe has been found in a fossil state, by Capt. Cautley and Dr. Falconer, in the Seewalik Hills in India. They have described it under the name *Siratherium*. The head is a gigantic resemblance of that of the Giraffe; as may be seen in the fine specimen preserved in the gallery of the British Museum.

GLASS-SNAKE. The name given in North America to a species of lizard, the *OPHISAURUS VENTRALIS*. It belongs to the family *ZONURIDÆ* of Mr. Gray, and has doubtless acquired its name from its "brittleness,"—a habit not uncommon with lizards of allowing their tails to be left in the hands of any who surprise them.

GLAUCOPTIS. A genus of birds belonging to the family *CORYTHIDÆ*; the only known species being the *GLAUCOPTIS CINEREA*, or NEW ZEALAND CROW. This bird, which has all the habits of a crow, is called by the natives of New Zealand *Kokako*. Its plumage is a very dark green, not much varied in any part of the body; the legs are black and coarse, the claws long. It has a strong black beak, a little curved; and a small brilliant light-blue flap hanging down on each side from the ear; the colour of these flaps fades, however, immediately the bird is dead, and becomes of nearly the same hue as its plumage.

GLAUCUS. A genus of molluscons animals found in the warmer latitudes floating in the open sea, and remarkable for their beautiful azure blue and silvery tints. They are about one inch and three quarters in length, with a subcylindrical body, and the tail terminating in a sharp point, the head furnished with four very short tentacula, and the sides of the body having tufts or branchiæ disposed in pairs, surrounded by digitated appendages, fitted for swimming.

GLIRES. (Lat. *glis*, a dormouse.) The fourth order of Mammalia in the Linnean system, distinguished by two flat incisors in each jaw. They are also called *RODENTIA*, or *GRAWEES*.

GLOBE-FISH. [See *DIDON* and *TETRAODON*.]

GLOMERIS. A myriapod bearing a strong resemblance to the woodlouse, in its oval form, and its habit of rolling itself into a ball. [See *MYRIAPODA* and *ZEPHEONIA*.]

GLOW-WORM. (*Lampyrus noctiluca*). This curious and interesting insect (the female of which, being expressly called by this name), is seen during the summer months,

as late as the close of August, on dry banks, about woods, pastures, and hedgerows, exhibiting, as soon as the dusk of the evening commences, the most vivid and beautiful phosphoric splendour. The male insect is

GLOW-WORM.—(LAMPYRIS NOCTILUCA.)

rather more than half an inch in length; the head is of a dun colour, the thorax margined with dusky red, as are also the legs and the edges of the segments of the body; and the wings are shorter than the body. The female is wingless, but in most other respects resembles the male: the thorax is semicircular; the body is very soft, of an oblong form, and pointed at the extremity. It is hardly yet determined with certainty whether the male Glow-worm is at all luminous; but it is universally understood that if it be, it is in a very slight degree. The phosphorescent light emitted by the female, and which can be increased or lessened at will, proceeds from the abdomen, near the tail; it is of a yellow colour, with a very slight cast of green. The larva, pupa, and complete female insect scarcely differ perceptibly from each other in general appearance, but the phosphoric light is strongest in the perfect animal. The general idea among naturalists is, that the light emitted by the female is for the purpose of attracting the other sex; and in numerous instances have poets availed themselves of so pleasing a simile as "the Glow-worm's amorous fire," to illustrate the pure intensity of that flame which so often burns in a heroine's breast. Dismissing the poetical metaphor, however, we may observe that the Glow-worm is a slow-moving, inactive insect, and its light not perceptible in the day-time, even if carried into a darkened room, unless the creature is turned on its back, and put in motion; but as night advances, its lamp again begins to burn. On this subject Mr. Knapp remarks, that on a warm dewy evening at the end of September he observed on the house-bank multitudes of these small evanescent sparks in the grass. "The number of them and their actions, creeping away from our sight, contrary to that half-lifeless dullness observed in summer, suggested the idea that the whole body had availed themselves of this warm moist evening to migrate to their winter station. A single spark or so was to be seen some evenings after this, but no such large moving parties were to be discovered again. If we conclude that the summer light of the glow-worm is displayed as a signal taper, the appearance of this autumnal light can have no such object in view, nor can we rationally assign any use of it to the creature itself, unless, indeed, it serves as a point of union

in these supposed migrations, like the leading call in the flight of night-moving birds. The activity and numbers of these insects, in the above-mentioned evening, enabled me to observe the frequent presence and disappearance of the light of an individual, which did not seem to be the result of will, but produced by situation." (See LAMPYRIS: ELATER.)

GLUTTON. (*Gulo arcticus*.) A carnivorous quadruped, of a very voracious nature, and about the size of a large Badger; between which animal and the Polecat it seems to be intermediate; nearly resembling the former in its general figure and aspect, and agreeing with the latter as in its dentition. The muzzle, beyond the eyes, is blackish brown, covered with hard shining hair; between the eyes and ears runs a whitish or ash-coloured band or fillet; the top of the head and back are black-brown, the sides inclining to a chestnut colour; and the feet are black. These animals are slow and comparatively deficient in agility; but they are very persevering, determined, and cunning. In the northern regions, both of the Old and New World, they are said to be of

SKULL OF GLUTTON.
(GULO ARCTICUS.)

uncommon fierceness and strength, sometimes even disputing their prey with the Wolf and Bear. They often proceed at a steady pace for miles, hunting out weak or dying animals, and stealing unawares upon hares, marmots, birds, &c. They are said to surprise the larger quadrupeds, such as the Rein-deer and the Elk, as they lie asleep; and to tear the neck and throat in the same manner as the Weasel. What they cannot devour at once they are said to hide under ground or in a hollow tree. They prefer putrid flesh, and are extremely fetid. The female brings forth two young at a litter once a year. The fur is much used for muffs, linings, &c.; and the skins brought from Siberia are much preferred to others, from their being of a more glossy black. This animal is also called the WOLVERENE.

GLYCIPHILA. A genus of Tenuirostral birds belonging to the family *Meliphagidae*, of which we may mention *GLYCIPHILA FULVIFRONS*, or the **FULVOUS-FRONTED HONEY-EATER**. This species, Mr. Gould observes, differs sufficiently from the true *Meliphaga* to fully justify its separation into a distinct genus. It prefers to dwell among the trees that crown the low stony ridges, rather than those growing on the lower lands or the

brushes; its flight is rapid, it mounts high in the air, and flies off to a distance with an extremely rapid horizontal and even motion. The song is rather remarkable, being commenced with a single note slowly drawn out, and followed by a quick repetition of a double note, repeated several times in succession, and mostly uttered when the bird is perched on the topmost branch of a tree. It is an exceedingly active bird among the branches, gracefully clinging about and around the flowers of the *Eucalypti* in search of food. It builds in some low bush or scrubby plant, near the ground, the nest being of a compact cup-shaped form, constructed of dried grasses, and lined with soft wool. The eggs are rather large, and often much lengthened; sometimes quite white, but more generally blotched with large marks of chestnut-red. It feeds on the pollen of flowers and insects.

GLYPTODON. The name given to an extinct quadruped, of gigantic dimensions, which, like the *Armadillos* of the present day, was covered with a tessellated bony armour. In size it was equal to the *Rhinoceros*. Prof. Owen has published an elaborate memoir on it, which is beautifully illustrated. The fine specimen in the College of Surgeons must strike every visitor by its dimensions, curious characters, and state of preservation. It was found in South America.

GNAT. (*Culex*.) The *Culicidae*, or Gnat tribe, are a family of Dipterous insects, whose mouths are furnished with bristly stings, included in flexile sheaths. Some of the species are extremely troublesome, as they pierce the skin to feed upon the blood, and at the same time inject an irritating poisonous fluid. Their flight is accompanied by a humming noise, occasioned by the vibration of their wings; they seldom appear in the day-time, except in thick woods, and they abound in moist situations, which is easily accounted for by their larvæ being inhabitants of the water. In this state they are very active, swimming with great agility, and often descending; but coming to the surface to breathe, which they do head downwards, the respiratory orifice being at the end of a very prolonged spiracle arising from the end of the abdomen. — That well-known insect the **COMMON GNAT** (*Culex pipiens*) is produced from a singular-looking aquatic larva: it has a large head, furnished on each side with a pair of antennæ-like jointed processes; the thorax large and angular; the body suddenly lessening from this part, and continuing of nearly the same size to the tail, which is abruptly truncated, and tipped with four foliaceous processes. In about fifteen days' time the larvæ are full grown, and arrive at the pupa state; the animal then appears to have a rounded form, is very active, and still inhabits the water; the position of its breathing apparatus, however, is now altered, being situated at the anterior part of the body, and consists of two little tubes, which are applied to the surface of the water for the reception of air. When ready to assume the perfect state, it rises to

the surface, and the Gnat quickly emerges from its confinement. A warm, rainy season is most favourable to the evolution of Gnats; and, in such summers, particular districts in most countries are occasionally pestered by them in countless swarms. Those persons who inhabit the more favoured regions of the European continent can hardly conceive what torments are endured from them in some parts of the world; but of all people the Laplanders appear to be the greatest sufferers; for during the heats of their short summer, the Gnats fill the air with such swarming myriads, that the poor inhabitants can hardly venture to walk out of their cabins, without having first smeared their hands and faces with a composition of tar and cream, which is found by experience to prevent their attacks.

A very small black Gnat (*Culex reptans*), with transparent wings, and the legs marked by a white bar, is particularly troublesome in marshy districts during the evening, by its creeping motion on the skin of the face, &c.

To the above we may add, that the Mosquito (*Culex mosquito*), so much dreaded by all who visit the West Indies and America, where its bite seems to operate with peculiar malignity, is a species of Gnat which derives additional vigour from the warmer and moister atmosphere. But it is not wonderful that in uncultivated wastes, where the waters stagnate, and the heat of the sun is almost insupportable, that the atmosphere should frequently be filled with clouds of these insects, varying in size from three or four inches in length to a minuteness only discernible by the assistance of a microscope. [See Mosquito.]

GNATHODON. A genus of bivalve shells, of which there is one well-known species, (*Gnathodon cuneatus*), from New Orleans. It is ovate, equivalve, and equilateral; and is known from all other shells by the characters of the hinge, having in one valve, a sharp, angular, notched, cardinal tooth, and two lateral teeth, the posterior of which is elongated, and the anterior angulated, tortuous, shaped like a jawbone; in the other valve, two cardinal and two lateral teeth, the interior of which is wedge-shaped. Ligament internal, coniform; muscular impressions two. The name has also subsequently been given to a genus of birds. [See next article.]

GNATHODON. A genus of birds described by Sir W. Jardine, from a specimen which belonged to Lady Harvey. From the contour of its beak, which has the upper mandible strongly hooked, as in the Dodo, and the under mandible deeply notched, it is supposed by Mr. Gould to be frugivorous or granivorous; the beak being expressly adapted to denude palm nuts, or other strongly coated seeds, of their hard outer covering. Mr. Gould considers that it is more nearly allied to the Pigeon tribe (*Columbidae*) than to any other family; the form of the body and wings, and the structure of the feathers, indicating this affinity. The only known species, *Gnathodon strig-*

rostris, is rather larger than a partridge, and has the head, neck, breast, and belly, of a glossy green black; the back, wings, tail,

ONATHODON SIAIROSTRIUS.

and under tail-coverts, of a deep chestnut red: the beak and naked part round the eye are of a yellowish colour. It is believed to be a native of one of the South Sea Islands; and the *Dilunculus*, found by the recent American Voyage of Discovery under C. Wilkes, is thought to be the same bird.

GNU. (*Boselaphus Gnu.*) A very singular species of Antelope, which, at first sight, appears to be a monstrous being, compounded of parts of different animals. Its general colour is a deep umber-brown, approaching to black. It is four feet in height, having the body and crupper of a small horse, and is covered with brown hair; the tail is furnished with long white hairs (like a horse), and on the neck is a beautiful flowing mane, white at the base, and black at the tips. Its horns, approximated and enlarged at the base, descend outwardly, and turn up at the point; the muzzle is large, flat, and surrounded by a circle of projecting hairs; under the throat and dewlap is another black mane; and the legs are as light and slender as those of a stag. The Gnus inhabit the wild karroos of South Africa and

GNU.—(BOSELAPHUS GNU.)

the hilly districts, where they roam mostly in large herds, and migrate according to the season. They are naturally wild and difficult of approach; and when first alarmed, they fling up their heels and plunge about like a restive horse: they soon, however, take to flight, and traverse the desert with such astonishing celerity—not in a tunnel-

tuons mass, but in single file, following a leader—that they are quickly out of danger. When wounded they will sometimes turn upon the hunter and pursue him in turn, darting forwards on their assailant with amazing force and impetuosity, so that it requires the utmost coolness on his part to evade the attack. When taken young, this animal is easily domesticated.

GOAT. (*Capra hircus.*) The distinguishing characters in the genus *Capra* in the Linnæan system of Zoology are,—that the horns are hollow, turned upwards, and annulated on their surfaces; that there are eight cutting teeth in the lower jaw, and none in the upper; and that the male is generally bearded. In its domestic state the Goat is found in almost every part of the globe, bearing the extremes of heat and cold, and differing in size and form according to various circumstances; the horns generally having a curvature outwards towards the tips.

Buffon's account of this animal is strikingly descriptive. "The Goat," says he, "is superior to the sheep both in sentiment and dexterity. He approaches man spontaneously, and is easily familiarized. He is sensible of caresses, and capable of a considerable degree of attachment. He is stronger, lighter, more agile, and less timid than the sheep. He is a sprightly, capricious, wandering, wanton animal. It is with much difficulty that he can be confined and he loves to retire into solitude, and to climb, stand, and even sleep, on rugged and lofty eminences. He is robust and easily nourished, for he eats almost every herb, and is injured by very few. His bodily temperament, which in all animals has a great influence on the natural disposition, is not essentially different from that of the sheep. These two animals, whose internal organization is almost entirely similar, are nourished, grow, and multiply in the same manner; and their diseases are the same, excepting a few, to which the Goat is not subject. The Goat fears not, like the sheep, too great a degree of heat. He cheerfully exposes himself to the sun, and sleeps under his most ardent rays without being affected with the vertigo or any other inconvenience. He is not afraid of rain or storms; but he appears to feel the effects of severe cold. The inconstancy of his disposition is marked by the irregularity of his actions. He walks, stops short, runs, leaps, approaches or retires, shows or conceals himself, or flies off, as if actuated by mere caprice, and without any other cause than what arises from an eccentric vivacity of temper. The suppleness of his organs, and the strength and nervousness of his frame, are hardly sufficient to support the petulance and rapidity of his natural movements."

The original stock of the Common Goat, as of other races of animals early subjugated by Man, cannot be distinctly traced; but it appears to be the same with that of numerous half-domesticated breeds, which abound in Asia. Mr. Bell, in his History of British Quadrupeds, remarks, that "most modern

zoologists who have paid much attention to the question, and who have brought to the consideration of it all the helps which recent discoveries in philosophical zoology have furnished, have leaned to the belief that the *Ægagrus*, or Wild Goat of the mountains of Caucasus and of Persia, is the true original stock. The zoological characters of this animal certainly bear a closer resemblance to those of the domestic breeds; and it is worthy of remark, that the horns of the Persian Domestic Goat, though smaller, are similar in form to those of the *Pascus* or *Ægagrus*. The arguments which have been urged from the intermixture of the *Iber* with the Common Goat are at present of little value; as the facts recorded are very deficient. The large Goats which are reported to have been brought from the Alps and the Pyrenees to the Garden of Plants in Paris, and which were stated to have been wild, were probably the progeny of the *Iber* with the Common Goat, as there is no proof of the existence of the true *Ægagrus* in Europe. These were found to be capable of producing offspring, and the details are given by Mr. Fred. Cuvier with great clearness; but the old fault still remains; the question is not set at rest by these observations; for we are only informed that they produce offspring, without any statement whether they will breed *inter se*, or only with the Common Goat. The progeny, however, were either prematurely brought forth, or lived only a short time in a sick and languishing condition."

"The condition of the Goat, in some parts of our own islands," says the same intelligent and accurate writer, "is much more wild than that of any other of our domestic animals. In the mountains of Wales especially the Wild Goats roam over the most inaccessible parts of the mountains and rocks, without the slightest appearance of domestication, or of having been deduced from a domestic stock. It is a hardy, active, powerful animal; capable of maintaining its footing on the smallest point on which its feet can possibly rest, and of taking considerable leaps with the utmost certainty of safely alighting, although the spot which it desires to attain be perhaps but the rugged point or ledge of a precipice. It will thus find its food in places inaccessible to almost all other animals, and live and thrive by cropping the scanty herbage which they furnish. In the mountain ranges of Europe, on the Alps and Pyrenees, the Goat is found at a great elevation, approaching as near the line of perpetual snow as it can find the scanty means of its sustenance; and it feeds on many plants which to other ruminants are distasteful, and even deleterious: thus, hemlock, henbane, and digitalis is eaten by it with impunity, and even the acrid euphorbia is not rejected."

The milk of the Goat is sweet, nutritive, and medicinal; this may be accounted for from the animal's food being chiefly derived from the heathy mountains and shrubby pastures, where sweet and aromatic herbs abound. In ancient times the skin of the Goat was regarded as a most useful article of

clothing: it is still manufactured into the best Turkey or Morocco leather; while that of the kid (whose flesh is regarded as a delicacy) forms the softest and most beautiful leather for gloves, &c. The usual colour of the domestic Goat is black and white, or a pale reddish-brown, with a black stripe down the back; but sometimes brown, white, or spotted. In old males the beard is very long; and the horns, which are transversely rugose, bending outwards and falling back, are sometimes nearly three feet long.

We find that the Common Goat inhabits most parts of the world, either native or naturalized. It endures all kinds of weather, being found in Europe as high as Wardhuys, in Norway, where it feeds during the winter season on moss, the bark of fir trees, and even of logs intended for fuel. It is also asserted that they thrive equally well in the hottest parts of Africa and India. The odour of the Goat, which at all times is proverbially strong, is intolerably so in the rutting season (from September to November); but it is commonly believed that horses are refreshed by it, which accounts for this animal being often kept about stables. Upon this subject Mr. Bell observes, "Many persons keep Goats in their stables, from an idea that they contribute to the health of the horses; a fancy not perhaps so far-fetched or absurd as at first sight it might appear; for I believe that all animals are kept in better temper and greater cheerfulness by the presence of a companion than in solitude, and the active and good-humoured Goat may in this way really perform the benefit which has been attributed to it upon mistaken grounds;—indeed, instances of close attachment between the horse and the stable Goat are not unfrequent." The female goes five months with young, and usually produces two kids at a birth; sometimes, however, three, and occasionally but one.

The ANGORA GOAT (*Capra Angorensis*) is by far the most elegant of all the varieties of the Goat, and is a native of Angora, a small district of Asia Minor, and remarkable for producing not only this peculiar race of goats, but also sheep, cats, rabbits, &c., with hair of uncommon fineness. The Goat of Angora is generally of a beautiful milk-white colour, short legged, with black, spreading, spirally-twisted horns, and pendulous ears. Its chief and distinguishing excellence, however, is the wool, which covers the whole body in long pendent spiral ringlets; and it is from the hair of this animal that the finest camlets are made.

The CASHMIRE GOAT, so highly prized for its fleece, is descended from the Goat of Thibet, which pastures on the Himalaya. It is smaller than the common domestic Goat, and has long, fine, silky wool. Thibet is situated at the northern descent of the Himalayan mountains, and Cashmere at the southern; hence there is some difference in the climate; it is observed, also, that the colder the region where the animal pastures, the heavier and finer is its fleece. The Goats which pasture in the highest vales of

Thibet are of a bright ochre colour; in lower grounds, the colour becomes of a yel-

CASHMERE GOAT.

lowish-white, and still farther downwards entirely white. The highest mountains of the Himalaya inhabitable by man contain also a species of black Goats, the wool of which as a material for shawls in India obtains the highest price. The Goats of Thibet and Cashmere have the fine curled wool close to the skin, just as the under hair of our common Goat lies below the coarse upper hair. The flesh of the Cashmere Goat tastes as well as that of the common one; and its milk is as rich; but these animals owe their great celebrity to the extraordinary beauty and costliness of the shawls for which the Asiatics have been so long famous.

The SYRIAN GOAT is remarkable for its large pendulous ears, which are usually from one to two feet in length, and sometimes so troublesome to the animal, that the owners are obliged to trim them, to enable it to feed more at ease. The horns are black, bending a little forwards; and are only about two inches long. The colour of its hair is like that of a fox; and there are two fleshy excrescences under its throat. This variety appears to have been known to Aristotle.

There are several other varieties of the Goat which it is needless to enumerate. But there is one species in North America (the ROCKY MOUNTAIN GOAT), which we should notice, inasmuch as it has given rise to much difference of opinion as to its proper place in a system of arrangement. It has been designated *Ovis montana*. The Rocky Mountain Goat nearly equals in size a common sheep, and has a shaggy appearance, in consequence of the protrusion of the long hair beyond the wool, which is white and soft. Its horns are about five inches long, conical, somewhat curved backwards, and projecting but slightly beyond the wool of the head. They are in great numbers about the head waters of the Columbia, and furnish the principal part of the food of the natives of that district. They appear to be more numerous on the western than on the eastern side of the mountains, and are rarely seen in the plains. The skin is very thick and spongy, and is principally used in making moccasins. Next to the fleece of the Cashmere Goat this is believed

to be the finest; and it is prized accordingly.

GOAT-MOTH. [See *COSSUS LIGNIPERDA*.]

GOATSUCKER, or NIGHT-JAR. (*Caprimulgus Europæus*.) There are many species of Goatsuckers, but this is the only one of the genus that inhabits Europe permanently, the *Caprimulgus ruficollis* being confined to South Western Europe, and appearing there only in the summer. With us it is only a summer visitant, appearing about the middle of May, and retiring in September or October. Before, however, we give a description of the bird, it may be as well to observe that the name *Goatsucker*, although very generally used, and retained in most ornithological works, has no foundation but in the ignorance and superstition of the ancients, who believed it sucked the teats of goats; on which account Bewick suggests the propriety of dropping the

NIGHT-JAR. — (*CAPRIMULGUS EUROPEUS*.)

name, and adopting that of NIGHT-JAY, "which, though not universally known, bears some analogy to the nature and qualities of the bird, both in respect to the time of its appearance, which is always the dusk of the evening, as well as to the jarring noise it utters whilst at rest perched on a tree, and by which it is peculiarly distinguished." Like the Owl, it is seldom seen in the daytime, unless disturbed, or on dark and gloomy days, when its eyes are not dazzled by the bright rays of the sun. As moths, gnats, beetles, and other night insects are its food, it is peculiarly formed to enable it to catch them on the wing. For this purpose nature has bestowed on it a mouth of great comparative size, which as the Goatsucker flies, it can quickly open, while the insects are additionally secured by the bill being surrounded on the inner side with a glutinous substance that prevents their escape. This manner of flying with its mouth open is the cause of that whirring noise which this bird makes while chasing its prey. It arises from the resistance made to the mouth by the air; and is more or less loud according to the velocity with which the bird moves. When

perched, it usually sits on a bare twig, with its head lower than its tail, and in this attitude, utters its jarring. It does not perch like other birds, sitting across the branch, but lengthwise, and its hinder toe is capable of being turned forward as well as backward. It is solitary in its habits, and is generally seen alone.

The colours of this bird, though plain, have a beautiful effect from the elegance of their disposition, the plumage being beautifully freckled, barred, and spotted with browns, black, grey, and ferruginous, variously arranged and diversified. The bill is small, flat, and hooked at the tip; the eyes are large, full, and black; the legs are short, rough, and scaly, and feathered below the knee: the toes are connected by a membrane as far as the first joint; the middle one is considerably longer than the rest, and the claw is serrated on one side. The use of this peculiar organ is not clearly ascertained; by some it is affirmed that the bird employs it to clear away the fragments of insects that may have clogged up the fringe of bristles; by others, that it strikes its prey with its foot, and that this long serrated claw enables it to hold the insect more securely; and by others again, that it uses it to clean its plumage. The male is distinguished from the female by an oval white spot, near the end of the first three quill-feathers. These birds frequent moors and wild leathery tracts abounding in fern; they make no nest, but the female deposits her eggs, which are of a dull-white colour, on the ground. Montbellard, who wrote this bird's history for Buffon, states, that it no sooner perceives its retreat to be discovered by an enemy, than it carefully rolls its eggs to a more secure situation.

There are other species bearing the same general appellation; one of which is known in America as *Whip-poor-Will*; another as *Chuck-Will's-Widow*, a third as the *Night-hawk*, and a fourth as the *Rain-bird*. There are also the *Banded Goatsucker*, and *Crested Goatsucker*, natives of New Holland; besides several inhabiting various parts of India, Africa, &c. These are placed in different genera: for descriptions of figures of which we refer our readers to the works of Mr. Gould, and of Messrs. Gray and Mitchell. The two first-mentioned we shall here describe, from Wilson.

WHIP-POOR-WILL. (*Caprimulgus [Antrostomus] vociferus.*) The notes of this solitary and celebrated bird, when first heard in the spring, at evening twilight or morning's dawn, seem like the voice of an old friend, and are listened to by almost all with great interest. At first they issue from some retired part of the woods, the glen, or mountain; in a few evenings, perhaps, we hear them from the adjoining coppice, the garden fence, the road before the door, and even from the roof of the dwelling-house, long after the family have retired to rest. He soon becomes a regular acquaintance. Every morning his shrill and rapid repetitions are heard from the adjoining woods; and when two or more are calling out at the same time, as is often

the case in the pairing season, and at no great distance from each other, the noise, mingling with the echoes from the mountains, is really surprising. Their notes seem pretty plainly to articulate the words which have been generally applied to them, *Whip-poor-*

WHIP-POOR-WILL.
(*CAPRIMULGUS VOCIFERUS.*)

Will, the first and last syllables being uttered with great emphasis, and the whole in about a second to each repetition; but when two or more males meet, their whip-poor-will alternations become much more rapid and incessant, as if each were straining to overpower or silence the other. When near, you often hear an introductory cluck between the notes. At these times, as well as at almost all others, they fly low, not more than a few feet from the surface, skimming about the house and before the door, alighting on the wood-pile, or settling on the roof. Towards midnight they generally become silent, unless in clear moonlight, when they are heard with little intermission till morning. If there be a creek near, with high precipitous hushy banks, they are sure to be found in such situations. During the day they sit in the most retired, solitary, and deep-shaded parts of the woods, generally on high ground, where they repose in silence. When disturbed, they rise within a few feet, sail low and slowly through the woods for thirty or forty yards, and generally settle on a low branch or on the ground. Their sight appears deficient during the day, as, like owls, they seem to want that vivacity for which they are distinguished in the morning and evening twilight. They are rarely shot at or molested; and from being thus transiently seen in the obscurity of dusk, or in the deep umbrage of the woods, no wonder their particular markings of plumage should be so little known, or that they should be confounded with the Night-hawk, whom in general appearance they so much resemble. The female begins to lay about the second week in May, selecting for this purpose the most unfrequented part of the wood, often where some brush, old logs, heaps of leaves, &c. had been lying, and always on a dry situation. The eggs are deposited on the ground, or on the leaves, not the slightest appearance of a nest being visible. These are usually two or three in number, in shape much resembling those of the Night-hawk, but having the ground colour much darker, and more thickly marbled with dark olive.

The Whip-poor-Will is nine inches and a half long, and nineteen inches in extent; the bill is blackish, a full quarter of an inch long, and bent a little at the point, the under mandible arched a little upwards; the nostrils are prominent and tubular, their openings directed forward; the mouth is extravagantly large, of a pale flesh colour within, and beset along the sides with a number of long, thick, elastic bristles, which end in fine hair, and curve inwards; these seem to serve as feelers; and prevent the escape of winged insects: the eyes are very large, full, and bluish black; the plumage above is so variegated with black, pale cream, brown, and rust colour, sprinkled and powdered in such minute streaks and spots, as to defy description; the upper part of the head is of a light brownish gray, marked with a longitudinal streak of black, with others radiating from it; the back is darker, finely streaked with a less deep black; the scapulars are very light whitish ochre, beautifully variegated with two or three oblique streaks of very deep black; the tail is rounded, the three outer feathers on each side are blackish brown for half their length, thence pure white to the tips; the deep brown of these feathers is regularly studded with light brown spots; the four middle ones are without the white at the ends, but beautifully marked with herring-bone figures of black and light ochre finely powdered. The cheeks and sides of the head are of a brown orange colour; the wings, when shut, reach scarcely to the middle of the tail, and are elegantly spotted with very light and dark brown; chin black, streaked with brown; a narrow semicircle of white passes across the throat; breast and belly irregularly mottled and streaked with black and yellow ochre, legs and feet light purplish flesh colour, scamed with white; the former feathered before, nearly to the feet; the two exterior toes are joined to the middle one, as far as the first joint, by a broad membrane; and the inner edge of the middle claw is pectinated, and therefore probably employed as a comb to rid the plumage of its vermin. The female is about an inch less in length and in extent, and differs also in being much lighter on the upper parts. Their food appears to be large moths, grasshoppers, ants, and such insects as frequent the bark of old rotten and decayed timber: they are also expert in darting after winged insects. They will sometimes skim in the dusk, within a few feet of a person, uttering a kind of low chatter as they pass. In their migrations north, and on their return, they probably stop a day or two at some of their former stages, and do not advance in one continued flight. This bird, like the owl and other nocturnal flyers, is regarded with a kind of suspicious awe by the weakminded and superstitious. "Night," says Wilson, "to minds of this complexion, brings with it its kindred horrors, its apparitions, strange sounds, and awful sights; and this solitary and inoffensive bird being a frequent wanderer in these hours of ghosts and hobgoblins is considered by the Indians as being, by habit and repute, little better than one of them."

The CHUCK-WILL'S-WIDOW. *Caprimulgus [Antrostomus] Carolinensis.* This species is twelve inches long, and twenty-six in extent; bill yellowish, tipped with black; the sides of the mouth are armed with numerous long bristles, strong, tapering, and furnished with finer hairs branching from each; cheeks and chin rust colour, speckled with black; over the eye extends a line of small whitish spots; head and back very deep brown, powdered with rust and cream colour, and marked with long ragged streaks of black; scapulars broadly spotted with deep black, bordered and in-

CHUCK-WILL'S-WIDOW.
(CAPRIMULGUS CAROLINENSIS.)

terspersed with a creamy white: the plumage of that part of the neck which falls over the back is long, something like that of a cock, and streaked with yellowish brown; wing quills barred with black and bright rust; tail rounded, extending about an inch beyond the tips of the wings; the middle feathers being powdered with various tints of ferruginous, and elegantly marked with fine zig-zag lines, and large herring-bone figures of black; exterior edges of the three outer feathers barred like the wings, their interior vanes being pure snowy white, marbled with black; across the throat is a slight whitish band; breast black, powdered with rust; belly and vent lighter; legs feathered before nearly to the feet, which are of a dirty purplish flesh-colour.

The Chuck-Will's-Widow, whose notes seem exactly to articulate these words, commences its singular call generally in the evening, soon after sunset, and continues it, with short occasional interruptions, for several hours. This note, or call, instantly attracts the attention of a stranger, and is strikingly different from that of the Whip-poor-Will. In sound and articulation it seems plainly to express the words which have been applied to it (*Chuck-Will's-Widow*), pronouncing each syllable leisurely and distinctly, putting the principal emphasis on the last word. In a still evening it may be heard at the distance of nearly a mile, the tones of its voice being stronger and more full than those of the Whip-poor-Will, who utters his with much greater rapidity. The flight of this bird is low, skimming about at a few feet above the surface of the ground, frequently settling on old logs, or on the fences, and from thence sweeping around, in pursuit of various winged insects that fly in the night. Like the Whip-poor-Will, it prefers the declivities of glens and other deeply shaded places, making the surrounding mountains ring with echoes the whole

evening. The Chuck-Will's-Widow lays its eggs, two in number, on the ground, in the woods; they are of a dull olive colour, sprinkled with darker specks, and about as large as a pigeon's.

This singular genus of birds, formed to subsist on the superabundance of nocturnal insects, are exactly and surprisingly fitted for their peculiar mode of life. Their flight is low, to accommodate itself to their prey; silent, that they may be the better concealed, and sweep upon it unawares; their sight, most acute in the dusk, when such insects are abroad; their evolutions, something like those of the bat, quick and sudden; their mouths capable of prodigious expansion, to seize with more certainty, and furnished with long branching hairs, or bristles, serving as palisades to secure what comes between them. Reposing so much during the heats of day, they are much infested with vermin, particularly about the head, and are provided with a comb on the inner edge of the middle claw, with which they are often employed in ridding themselves of these pests, at least when in a state of captivity. Having no weapons of defence except their wings, their chief security is in the solitude of night, and in their colour and close retreats by day; the former so much resembling that of dead leaves, of various hues, as not to be readily distinguished from them even when close at hand. [See NIGHT-HAWK.]

GOBIOIDEÆ. A family of Acanthopterygious fishes, including the Blennies, Gobies, &c. They may be recognised by the slenderness and flexibility of their dorsal rays. They have an uniformly wide intestinal canal, and no pyloric caeca.

GOBY. (*Gobius*.) A genus of Acanthopterygious fishes, of which there are several species, of a small size, in general varying from three to six inches in length; but none of them are much esteemed for food. They are distinguished by their ventral and thoracic fins being united in their whole length, or at their bases. The spines of the dorsal

RED GOBY — (*GOBIUS ORIENTATOR*.)

fins are flexible; the openings of their ears, with four rays. Like the Blenny, they can live a long time out of water. Several species are found in the Mediterranean, American, and Indian seas: some also on our own coasts. Three or four will suffice for examples.

THE BLACK GOBY, OR ROCK-FISH. (*Gobius niger*.) This is an inhabitant of the Mediterranean and Northern seas, and also of the rocky parts of our own coast: it grows to the length of six inches; the body is soft, slippery, and slender; the head large, the cheeks inflated, and the lips very thick; the mouth is wide, and furnished with numerous

small teeth in each jaw, the lower of which is the longest. The ventral fins coalesce, and form a sort of funnel, by which these fish are said to affix themselves immovably to the rocks. The general colour of the fish is a dusky black, and the tail is rounded at the end.

THE LANCE-TAILED GOBY (*Gobius lanceolatus*) is distinguished by and named from the peculiar form of its tail, which is large in proportion to the fish, and sharp-pointed at the tip. The body is of a lengthened shape, and nearly of equal diameter throughout: the head is oblong, and truncated in front; the jaws of equal length, and armed with sharp teeth; and the body is covered with scales, those toward the tail being much larger than those on the upper parts. This is a West Indian species.

THE BLUE GOBY (*Gobius caeruleus*) is a highly beautiful, though very small species: colour fine blue, rather paler beneath: tail red, with a black border. From the brilliancy of its colours it appears, when swimming in a calm sea, during a bright sunshine, like a small tube of sapphire, tipped with carbuncle. It is found on the eastern coasts of Africa; and the Negroes use it as a bait for other fish.

THE SPOTTED GOBY (*Gobius minutus*) is about three inches long; the head is large; the irides blue; the mouth wide, with several rows of small pointed teeth, curving inwards; the dorsal fins distinct, pectoral and ventral fins large; tail a little rounded. The general colour is a pale yellowish-white, freckled with minute light brown specks, and occasionally a row of larger spots along the lateral line. It is frequently taken on our sandy shores in shrimpers' nets; it is also plentiful in the Thames, where it is called by the fishermen Polewig, or Polly-bait.

GODWIT. (*Limosa*.) There are several species of these Grallatorial birds. They are a timid, shy, and solitary tribe; characterized by a straight beak, longer than that of the snipes, sometimes slightly bent at the extremity, and by long legs, naked far above the knee. They live amidst the fens, salt marshes, and deep muddy places near the mouths of rivers; seldom remaining above a day or two in the same place, and often removing suddenly in a flock at night, when they fly very high. When pursued, they run with great speed, and scream as they rise. They subsist on worms and larvae, and their flesh is very excellent. They are migratory, and moult twice in the year.

THE COMMON GODWIT (*Limosa limosa*) is sixteen inches in length, and weighs about twelve ounces. The bill is four inches long, bent a little upwards, and black at the point: the head, neck, back, scapulars, and coverts are a dingy reddish pale brown, each feather being marked down the middle with a dark spot. The fore part of the breast is streaked with black; belly, vent, and tail white, the latter barred with black: the webs of the first six quill-feathers black,

edged on the interior sides with reddish brown: legs inclining to greenish blue. In the spring and summer the Godwit resides in the fens and marshes, where it rears its young; but when the winter sets in with severity, it seeks the salt-marshes and sea-shores.

The **RED GODWIT**. (*Limosa rufa*.) This species is not very common in Great Britain, but is found in the north of Europe, and is very plentiful in the fenny parts of North America, about Hudson's Bay, &c. It is larger than the Common Godwit, and is distinguished from it by the redness of its plumage; the head, breast, and sides being a bright ferruginous red, streaked on the head with brown, and marbled on the breast and sides with dusky, cinereous, and white; neck plain dull rusty red. The back, scapulars, greater and lesser coverts, are greyish brown; on the former, some of the feathers are barred and streaked with black and rufous, edged with pale reddish white; and a bar of white is formed across each wing by the tips of the greater coverts. The under parts are white, slightly spotted with brown. The legs are dusky, and bare considerably above the knees. Its flesh is reckoned delicious.

There are also the Great American Godwit, the Cinereous Godwit, the Black-tailed Godwit, the Red-breasted Godwit, &c., all more or less resembling the species above described.

GOLDEN-EYE [BUTTERFLY]. The name given by collectors to Butterflies of the species *Hipparchia pamphilus*.

GOLDEN WASPS, or GOLDEN-TAILED FLIES. (*Chrysis*.) The popular names for a tribe of Hymenopterous insects, which in the richness of their colours are said to "vie with the Humming-birds." They may be observed walking, but in a constant agitation and with great agility, upon walls and palings exposed to the heat of the sun. They are also found upon flowers. The body is elongated and covered with a solid skin; the hind wings are not veined, but the ovipositor is formed by the terminal segments of the abdomen, and terminated by a small sting; the antennae are filiform, elbowed, and vibratile. The abdomen, which in the female appears to be formed of only three or four segments, is flattened or vaulted beneath, and capable of being folded against the breast, when the insect assumes an orbicular form. They deposit their eggs in the nests of Solitary Mason-bees, or other Hymenoptera, their larvæ destroying those of these insects. [See *CHRYSINIDÆ*.]

GOLDFINCH. (*Fringilla carduelis*.) Of all the British Finches, none equal the Goldfinch in brilliant plumage and docility; hence it is one of those most frequently kept in captivity; for though its song is soft and pleasing, it is deficient in power. Its length, from the tip of the bill to the end of the tail, is five inches and a half; and the greatest expansion of its wings is nine inches. The bill is white, tipped with black;

the forehead and chin a rich scarlet, which is divided by a black line passing from each corner of the bill to the eyes; the cheeks are white; top of the head black, that colour extending downward from the nape on each side; the back, rump, and breast are of a fine pale tawny brown colour; belly white; the wings and tail are black, but the points of the primaries in both are white; a beautiful yellow stripe runs across the wings: the tail feathers are black, with a white spot on each near the end; legs pale flesh red. The male is distinguished from the female by the feathers on the ridges of the wings, which are of a deep black colour; while those of the hen are a dusky brown; and the black and yellow in the wings of the latter are less brilliant than in those of the male. The nest of the Goldfinch is small, but ex-

GOLDFINCH.—(*FRINGILLA CARDUELIS*.)

tremely beautiful; the outside consists of very fine moss curiously interwoven with wool, hair, and other materials; and the inside is lined with the down of thistles and other soft and delicate substances. The nest is often found in an orchard, large garden, or plantation, in an apple or pear tree, or carefully placed in some thick evergreen shrub—somewhere in the neighbourhood of Man, but not immediately within his view. The bird lays five or six white eggs, marked with deep purple spots at the larger end. They feed their young with caterpillars and insects; and the old birds feed on various kinds of seeds; particularly those of the thistle, dandelion, and groundsel.

Goldfinches are more easily tamed than other birds; and so reconciled will they in time become to their imprisonment in cages, that they appear as if in reality attached to them. If a young Goldfinch is brought up under a canary, a wood-lark, or any other singing-bird, it will readily catch their song. Goldfinches breed with the Canary; this intermixture, says Bewick, succeeds best between the cock Goldfinch and the hen Canary, whose offspring are productive, and are said to resemble the male in the shape of the bill, and in the colours of the head and wings, and the hen in the rest of the body. Beauty of plumage, observes Buffon, melody of song, sagacity, and docility of disposition, seem all united in this charming little bird, which were it rare, and imported from a foreign country, would be more highly valued.

GOLD-FISH. (*Cyprinus auratus*.) In the fresh waters of China, we are told, certain beautiful species of *Cyprinus*, distinguished for the splendid golden colour of the membrane lying immediately beneath the scales, are as frequent as the most common river fish are here. Nor, indeed, are they at this time either rare or uncommon in our own ponds, being quite naturalized, and breeding freely in open waters.

The colours of Gold-fish are liable to the greatest variations: some are marked with a fine blue, brown, or bright silver hue, but the usually predominant colour is that of a brilliant gold. As an article of food they are not used, and are only valued for their beauty and gentleness.

GOLIATHUS (GOLIATH BEETLES). A group of Lamellicorn Coleoptera, which are chiefly found in Africa, the largest species being indigenous to the western coasts. These insects, which were formerly very scarce, and some of which are still rare in collections, have acquired their name from the large size of some of the species. One of the first specimens was found by Mr. Ogilvie, surgeon of H. M. S. Renown, at least eighty years ago. The specimen was dead, and found floating in the river Guboon; it is now in Glasgow, in the Hunterian Museum.

MALE CACIQUE GOLIATH BEETLE
(*GOLIATHUS CACICUS*.)

The fine species figured above was believed, by its describer, Voet, to be a native of South America, and hence he called it *Cacicus*, after the native chiefs of that country.

The male differs from the female in the armature of the head and in the structure of the fore-legs, which are spineless on the outside, as is well shown in the figure.

The elytra of the male of the *GOLIATHUS CACICUS*, are of a pearly satiny white, with a black opaque spot on the shoulder; the crown of the head and the thorax being of a

tinny yellowish brown, with black longitudinal bands on the latter.

FEMALE CACIQUE GOLIATH BEETLE
(*GOLIATHUS CACICUS*.)

These insects are said to be roasted and eaten by the natives, who doubtless often make a *bonne bouche* of what would gratify many an entomologist.

The males of these insects, we are informed by Dr. Savage, are much more numerous than the females; and though the various species of the group cannot be said to be very abundant, yet they are so frequently brought over now, that the large prices of 30*l.* and even 50*l.*, which used to be asked for them, are now very much reduced; fine specimens, however, of some of the species still fetch 5*l.* or 6*l.*

Separated from them by slight generic characters, are two other groups, a male and female of one of which are figured beneath.

MALE POLYPHEMUS BEETLE.
(*GOLIATHUS POLYPHEMUS*.)

It is the *GOLIATHUS (MECTONRHINA) POLYPHEMUS*; of a dark green colour, banded and spotted with white. The male and female are very similarly marked, but the

distinctions in the head and fore leg may be plainly seen in the figures. The female of this species is generally regarded also as

FEMALE POLIPREMUS BEETLE.
(GOLIATHUS POLIPREMUS.)

much rarer than the male. This species, as well as one named after Dr. Savage by Dr. Harris of Boston, feeds upon a vine that climbs over very lofty trees. The insects wound the bark of the vine, and extract the juice; the vine being full of a fluid as tasteless and limpid as water.

There are several other genera and species of Goliath Beetles, of most of which there are specimens in the collection of the British Museum; but we must refer our readers to the works of Dr. Burmeister and Mr. Westwood for descriptions and figures of these, it being quite out of the scope of this work to particularize them, splendid as they are. A list of all the species of *Cetoniidae* (including the Goliath), with reference to figures, has been published, and will show how rich the Museum collection is.

The next species (figured beneath) is from West Africa also, and is of a most brilliant green colour; it is the *GOLIATHUS* (*DICRONORHINA*) *MICANS*. The shades on this species vary according as the insect is held to the light.

GLISTERING GOLIATH BEETLE.
(GOLIATHUS MICANS.)

This insect seems to be a native of Senegal and the Calabar coast.

The food of the Goliaths is fluid, like that of the *Cetonia* and *Trichia*: the long brushes on their maxillae, and the diverging rows of hairs that line their lower lips, are admirably fitted for absorbing liquid food, while their horny teeth afford these beetles additional means of obtaining it from the leaves and juicy stems of plants when the blossoms have disappeared. "Thus every new discovery in Natural History, when least expected, serves to increase the evidence of skilful contrivance and perfect adaptation of structure in all organised beings." With this admirable remark of Dr. Harris we conclude this article. [See *CETONIADÆ*: *DICRONOCEPHALUS*: *INCA*.]

GOLLACH. [See *ÆÆWIG*.]

GONEPTERYX. A genus of diurnal *Lepidoptera*, so named from its angled wings. The British species is found with very slight variation on the Himalaya mountains; it is the

GONEPTERYX RHAMNI, or **BRIMSTONE BUTTERFLY**. This gay and lively-coloured insect is one of the earliest among the *Papilionidæ* that makes its appearance; sometimes, in favourable weather, even as early as the middle of February. Mr. Knapp, in his *Journal of a Naturalist*, alludes to this butterfly:—

"The very first butterfly that will

— 'ajost repair,

And sport and flutter in the fields of air,'

is the Sulphur Butterfly (*Gonepteryx rhamni*), which in the bright sunny mornings of March we so often see under the warm hedge, or by the side of some sheltered copse, undulating and vibrating like the petal of a primrose in the breeze." As the spring advances they may be seen on the wing in the woods, meadows, and commons, in tole-

BRIMSTONE BUTTERFLY
(GONEPTERYX RHAMNI.)

erable plenty; and as there is a second brood which comes forth about August, there is no lack of them at any time till autumn summons them away. The male is of a pure sulphur-yellow above, and the female of a greenish-white; and in both sexes a small spot of orange occupies the centre of each wing, and a dusky spot at the base: the abdomen is black above and yellow beneath, its base and the thorax thickly clothed with long glossy white silken hairs: the legs are white; the antennae reddish. The caterpillar is green, with a paler line on each side of the belly, and very small scale-like black

dots on the back. It feeds on the buckthorn (*Rhamnus catharticus*). The pupa, or chrysalis, is green, very gibbous in the middle, and acuminate before: it is vertically suspended on a perpendicular branch, with a loose silken thread round it.

GONOPLAX, or ANGLED CRAB. A genus of decapod short-tailed Crustacea, of which one species is found in this country: it is the *G. angulata* of authors, the young of which has been described as a species of *Gelasimus*. In the male the fore legs are very long. For figures of this species see Dr. Leach's work, or that of Professor Bell, "The British Crustacea."

GOOSE. A genus of webfooted birds. The Common Wild Goose (*Anser ferus*), otherwise called the GREY LAG GOOSE, being the origin of our domestic species, we shall describe it first in order, after having made a few observations on the distinguishing characters of the genus. The bill is the first great distinction of the Goose kind from all the feathered tribes. In other birds it is round and wedge-shaped, or crooked at the end; in all the Goose kind it is flat and broad, formed for the purpose of skimming ponds and lakes of the mantling weeds which grow on their surface. The bills of other birds are composed of a horny substance throughout, formed for piercing or tearing; but birds of this genus have their inoffensive beaks sheathed with a skin which entirely covers them; and are only adapted for shovelling up their food, which is chiefly confined to vegetable productions: for though they do not reject animal food when offered to them, they contentedly subsist on vegetable, and seldom seek any other.

The GREY LAG, or COMMON WILD GOOSE, as Pennant remarks, is our largest species; the heaviest weigh ten pounds; the length is two feet nine inches; the extent five feet. The bill is large and elevated, of a flesh colour tinged with yellow; the nail white

WILD GOOSE, — (ANSER FERUS.)

the head and neck cinereous, mixed with ochraceous-yellow; the hind part of the neck very pale, and at the base of a yellowish-brown; the breast and belly whitish, clouded with gray or ash-colour; the back gray, the lesser coverts of the wings almost white, the middle row deep cinereous slightly edged with white; the primaries gray, tipped with black and edged with white; the

coverts of the tail and the vent feathers of a pure white; the breast and belly crossed and clouded with dusky and ash on a whitish ground; the middle feathers of the tail dusky, tipped with white, the exterior ones almost wholly white: the legs of a flesh-colour. This species is widely and numerously spread over all the more northerly parts of the globe, whence some flocks of them migrate a long way southward in the winter. Latham says, they seem to be general inhabitants of the world,—are met with from Lapland to the Cape of Good Hope,—are frequent in Arabia, Persia, and China, as well as indigenous to Japan,—and on the American continent from Hudson's Bay to South Carolina. As for their summer residences and breeding-places, the lakes, swamps, and dreary morasses of Siberia, Lapland, Iceland, and the unfrequented northern regions of America seem set apart for that purpose, where, with multitudes of other kinds, in undisturbed security, they rear their young, and are amply provided with a variety of food, a large portion of which must consist of the larvæ of gnats, which swarm in those parts, and the myriads of insects that are fostered by the unsetting sun.

These birds are often seen, in flocks of fifty or a hundred, flying at very great heights, and preserving very great regularity in their motions; sometimes forming a straight line, and at others assuming the shape of a wedge, which is supposed to facilitate their progress. Their cry is frequently heard when they are at an imperceptible distance above us. When on the ground, they range themselves in a line, after the manner of cranes; and seem to have descended rather for the sake of rest than for any other refreshment. Having continued in this situation for an hour or two, one of them, with a long loud note, sounds a kind of signal, to which the rest punctually attend, and rising in a group, they pursue their journey with renewed alacrity.

Their flight is conducted with singular regularity; they always proceed either in a line abreast, or in two lines joining in an angle at the middle, like the letter V. In this order they generally take the lead by turns, the foremost falling back in the rear when tired, and the next in station succeeding to his duty. Their track is generally so high that it is almost impossible to reach them from a fowling-piece; and even when this can be done, they fly so equally, that one discharge seldom kills more than a single bird. They are very destructive to the growing corn in the fields where they happen to alight in their migrations. In some countries they are caught at such times in long nets, to which they are decoyed by tame geese placed there for that purpose. Other schemes are contrived to take them; but as they are very vigilant, feed only in the day-time, and betake themselves to the water at night, the fowler must exert his utmost care and ingenuity in order to accomplish his ends; all must be planned in the dark, and every trace of suspicion removed; for nothing can exceed the wary circumspection

and acute ear of the sentinel, who, placed on some eminence, with outstretched neck, surveys everything that moves within the circle of his observations, and the instant he sounds the alarm, the whole flock betake themselves to flight.

But though they are seen regularly migrating southward in the autumn, and northward in the spring, they were formerly known to remain and breed in the fens of Lincolnshire and Cambridgeshire, and various other parts of Great Britain; the draining and cultivation of these marshy districts have now, however, nearly depopulated them of their former feathered inhabitants; but in lieu of the wild races, these localities are now teeming with domesticated ones in a highly improved condition. The Wild Goose lays from six to eight, sometimes ten or a dozen eggs, of a dirty greenish colour, the nest being placed among rushes, heaths, &c.

THE TAME GOOSE. The wild species we have just described is, as before stated, the original of the domesticated Goose; to describe whose varied plumage, economy, and habits, may to many seem a superfluous task; while others, to whom they are less well known, may deem the account sufficiently interesting. How long they have been reclaimed from their original independence is not easily ascertained; but the time must have been very remote, for from a very distant date they appear to have held their present station, to have been kept for the self-same purposes, and to have been treated in the same manner. Their predominant colours are white and gray, with shades of ash and brown: some of them are yellowish, others dusky, and many are found to differ very little in appearance from the original stock. The only permanent mark, which all the gray ones still retain, like those of the wild kind, is the white ring which surrounds the root of the tail. They are generally furnished with a small tuft on the head; and the most usual colour of the males (the Ganders) is pure white; the hills and feet in both males and females are of an orange red. By studied attention in the breeding, two sorts of these Geese have been obtained—a larger and a smaller sort; the former weighing from ten to upwards of fifteen pounds, and frequently much more. The smaller kind are more delicate eating; delicacy, however, is often not so much regarded as the bountiful appearance and savoury smell of a "fine fat goose" on the festive board. But it is not altogether on account of their use as food that they are valuable; their feathers, their down, and their quills, have long been considered as articles of more importance, and from which their owners reap more advantages. Pennant, in describing the methods used in Lincolnshire, in breeding, rearing, and plucking Geese, says, They are plucked five times in the year: first at Lady-day for the feathers and quills; which business is renewed for the feathers only, four times more between that and Michaelmas; he adds, that he saw the operation performed even upon goslings of six weeks old, from

which the tail feathers were plucked; and that numbers of the Geese die when the season afterwards proves cold. But this unfeeling process, as well as the care and attention which are bestowed upon the brood Geese while they are engaged in the work of incubation, is nearly the same everywhere. Wicker pens are provided for them, placed in rows, and tier above tier. Some place water and corn near the nests; others drive them to the water twice a-day, and replace each female upon her own nest as soon as she returns. At length the brood is hatched, and as soon as they are able to follow their parent Geese, they are driven to the neighbouring fens and marshes, on whose grassy-margined pools they feed and thrive without requiring any further attendance until the autumn. In this way immense numbers are reared in many parts of this country; but nowhere are there so many as in the fens of Lincolnshire, where it is said to be no uncommon thing for a single person to keep a thousand old Geese, each of which, on an average, will bring up seven young ones. So far those only are noticed which may properly be called the larger flocks, by which particular watery districts are peopled; but it must be borne in mind that they form only a part of the large family; and when the stock of the various farm-yards throughout the kingdom are added, the immense whole will appear multiplied in a ratio almost incalculable. A great part of those which are left to provide for themselves during the summer, in the solitary distant waters, as well as those which enliven the village green, are put into the stubble fields after harvest, to fatten on the scattered grain, while some are penned up for this purpose; and at length vast numbers are driven in flocks, or otherwise sent, to the great mart and focus of consumption, London; the provincial towns throughout the kingdom being also furnished with an adequate supply.

The Tame Goose lays from seven to twelve eggs, and sometimes more; these are carefully divided among the brood Geese when they begin to sit: those which lay a second time in the course of the summer are seldom, if ever, permitted to have a second hatching; but the eggs are used for household purposes. It is universally believed that the Goose lives to a great age, and particular instances are recorded by ornithologists which confirm the fact—some even emulating the human period of "threescore years and ten."—It has been remarked that none of our domestic birds are so apt to bring forth monstrous productions as Geese—a circumstance which has been attributed to the excessive fatness to which they are liable. The liver of a fat Goose is often larger than all the other viscera, and was a dish in so great reputation among the epicures of Rome, that Pliny thought it deserved a serious discussion; to whom the honour of inventing so excellent a dish was due.

THE SNOW GOOSE (*Anser [Chen] hyperboreus*) is two feet eight inches in length, and its extended wings are five feet. The bill of this bird is very curious, the edges having each

twenty-three indentations, or strong teeth, on each side : the inside or concavity of the upper mandible has also seven rows of

SNOW GOOSE. — (ANSER HYPERBOREUS.)

strong projecting teeth ; and the tongue, which is horny at the extremity, is armed on each side with thirteen long and sharp bony teeth. The upper mandible of the beak is bright red, the lower whitish ; the hooks of both blue. The head, neck, and body are pure white : the quills are white for half their length, the rest black : the legs are of a very deep red. These birds inhabit the regions of the arctic circle, occasionally migrating to the more temperate climates of Prussia, Austria, Hudson's Bay, and the United States of America. They arrive in the River Delaware from the north early in November, sometimes in considerable flocks, and are very noisy : their note is more shrill than that of the Canada Goose. They make but a short stay in winter, proceeding farther south as the severity of the weather increases ; and early in the spring they retire to the polar regions, to perform the duties of incubation and rearing their young. Their flesh is esteemed excellent ; and in Siberia they form an essential article of subsistence to the natives, each family, it is said, preserving thousands annually.

The method adopted by the Siberians to obtain these Geese is highly curious. According to Pennant's account, they place near the banks of the rivers a great net in a straight line, or else form a hovel of skins sewed together : this done, one of the company dresses himself in the skin of a white rein-deer, advances towards the flock of Geese, and then turns backwards (on all fours) the net or hovel : and his companions go behind the flock, and, by making a noise drive them forwards. The simple birds mistake the man in white for their leader, and follow him within reach of the net, which is suddenly pulled down, and thus captures the whole. When he chooses to conduct them even into the hovel, they follow in the same manner ; he creeps in at a hole left for that purpose, and out at another on the opposite side, which he closes up. The Geese follow him through the first ;

and as soon as they are in, he passes round and secures every one of them.

The CANADA GOOSE, or CRAVAT GOOSE. (*Anser Canadensis*.) This is the common Wild Goose of the United States, and is known in every part of the country. It usually weighs about ten pounds. The general colour is a dark ash ; head, neck, and tail black ; cheeks and throat white ; bill and feet black. In their annual migrations to the north, it is the general opinion that they are on their way to the lakes to breed ; but, as Wilson observes, it is highly probable that they extend to the utmost polar point, amid the silent desolation of unknown countries, shut out from the prying eye of man by everlasting and insuperable barriers of ice. After having fulfilled the great law of nature, the approaching rigours of that dreary climate oblige them to return towards the more genial regions of the south ; and no sooner do they arrive among men, than an indiscriminate slaughter of them commences. The people at Hudson's Bay greatly depend on these birds, and, in favourable seasons, kill three or four thousand, which are packed up for future use. The autumnal flight lasts from the middle of August to November ; the vernal from the middle of April to the middle of May. Their mode of flying, the van being headed by an experienced old Gander, resembles that of the common Wild Goose before described. The Canada Goose generally builds its nest on the ground ; but some pairs occasionally breed on the banks of large rivers on trees, depositing their eggs in the deserted nests of ravens or fishing-cagles. The eggs, six or seven in number, are of a greenish white. The bird has been long domiciled in this country, where it breeds freely, and is a great ornament.

CANADA GOOSE. — (ANSER CANADENSIS.)

That most entertaining naturalist, Mr. Waterton, thus speaks of the Canada or Cravat Goose. "The fine proportions of this stately foreigner, its voice, and flavour of its flesh, are strong inducements for us all to hope that, ere long, it will become a naturalised bird throughout the whole of Great Britain. I stop not to give a detailed description of its plumage ; that has already been performed by many able hands. Suffice it then to say, that its beautiful black neck and white cheeks render it so particularly conspicuous, that those who have seen it

once will never be at a loss to recognise it, when viewed amongst all other species of the Goose tribe. There can be nothing more enlivening to rural solitude than the trumpet-sounding notes of the Canada Goose. They may be heard here at most hours of the day, and often during the night. But spring is the time at which these birds are most vociferous. Then it is that they are on the wing, moving in aerial circles round the mansion,—now rising aloft, now dropping into the water, with such notes of apparent joy and revelry, as cannot fail to attract the attention of those who feel an interest in contemplating Nature's wildest scenery." Mr. W. afterwards relates the following interesting story:—"On my return from Italy in the autumn of 1841, the keeper informed me that, in the preceding spring, one of the little Bernacle ganders, accompanied by an old Canadian Goose, had come on the island where the mansion stands, and formed a kind of nest on the border of a flower-bed near the boat-house; that the female had laid five eggs in it, and that all these eggs had turned out addle. I could easily comprehend the latter part of his information relative to the eggs; but had he told me that the income-tax is a blessing, and that the national debt is an honour to the country, I could more readily have believed him, than that a Canada Goose had been fool enough to unite herself with a Bernacle gander. Nevertheless the man persisted stoutly in what he had affirmed, and I told the story to others, and nobody believed me. In the breeding season, however, of 1842, this diminutive Gander and magnificent Goose appeared on the island; and as the spot which they had occupied on the preceding year was very bleak and quite unsheltered, I thought that I could offer them a more commodious situation. Just opposite the eastern windows of the sitting-room, and two-and-twenty yards distant from them, there is yet alive the remnant of a once superb and fertile black-heart cherry-tree. It was evidently past its prime in the days of my early youth; but I can well remember that it then bore ponderous loads of dainty cherries. This cherry-tree, like the hand that is now writing a description of it, appears the worse for wear; and the wintry blasts of more than half a century have too clearly proved that neither its internal vigour, nor the strength of its gigantic limbs, could make an effectual stand against the attacks of such sturdy antagonists. Its north-western and north-eastern parts have gradually died away, and what remains alive of it to the southward can no longer produce fruit to be compared with that of gone-by periods. The bole, too, which measures full ten feet and five inches in circumference at the graft, seems to show signs of Time's hard usage. Perhaps in a few years more a south-western gale, which often does much damage here, may lay it low in ruins. Close to this venerable tree I made a hollow in the ground, about the size of an ordinary coal-basket, and filled it with hay. The Geese soon took possession of it; and on the third day after they had occupied it, the female

laid an egg in it. She ultimately sat on five, and they all proved addle.

"Last year this incongruous though persevering couple visited the island again, and proceeded with the work of incubation in the same place, and upon hay which had been purposely renewed. Nothing could exceed the assiduity with which the little Bernacle stood guard, often on one leg, over his bulky partner, day after day, as she was performing her tedious task. If any body approached the place, his cackling was incessant: he would run at him with the fury of a turkey cock; he would jump up at his knees, and not desist in his aggressions until the intruder had retired. There was something so remarkably disproportionate betwixt this goose and gander, that I gave to this the name of Mopsus, and to that the name of Nisa; and I would sometimes ask the splendid Canadian Nisa, as she sat on her eggs, how she could possibly have lost her heart to so diminutive a little fellow as Bernacle Mopsus, when she had so many of her own comely species present, from which to choose a happy and efficient partner. The whole affair appeared to be one of ridicule and bad taste; and I was quite prepared for a termination of it, similar to that of the two preceding years, when behold! to my utter astonishment, out came two young ones, the remainder of the five eggs being addle. The vociferous gesticulations and strutting of little Mopsus were beyond endurance, when he first got sight of his long-looked-for progeny. He screamed aloud, whilst Nisa helped him to attack me, with their united wings and hissings as I approached the nest in order to convey the little ones to the water; for the place at which the old birds were wont to get upon the island lay at some distance, and I preferred to launch them close to the cherry-tree; which done, the parents immediately jumped down into the water below, and then swam off with them to the opposite shore. This loving couple, apparently so ill-assorted and disproportionate, has brought up the progeny with great care and success. It has now arrived at its full growth, and is in mature plumage. These hybrids are elegantly shaped, but are not so large as the mother, nor so small as the father, their plumage partaking in colour with that of both parents. The white on their front is only half as much as that which is seen on the front of the gander, whilst their necks are brown in lieu of the coal-black colour which appears on the neck of the goose. Their breasts, too, are of a dusky colour, whilst the breast of the Bernacle is black, and that of the Canadian white; and throughout the whole of the remaining plumage, there may be seen an altered and modified colouring not to be traced in that of the parent birds.

"I am writing this in the middle of February. In a fortnight or three weeks more, as the breeding season approaches, perhaps my little Mopsus and his beauteous Nisa may try their luck once more, at the bole of the superannuated cherry-tree. I shall have all in readiness, and shall be glad to see

them. I certainly acted rashly, notwithstanding appearances, in holding this faithful couple up to the ridicule of visitors who accompanied me to the spot where the novel incubation was going on. I have had a salutary lesson, and shall be more guarded for the future in giving an opinion. Information is always desirable, and is doubly satisfactory when accompanied by a demonstration. In the present instance, my speculation that a progeny could not be produced from the union of a Bernacle gander with a Canada goose has utterly failed. I stand convinced by a hybrid, reprimanded by a gander, and instructed by a Goose." [See *BERNACLE*.]

THE SWAN GOOSE. (*Anser cygnoides*.) This bird is of a size between the Swan and the common Goose, and is distinguished from other species by its upright and stately walk, by having a large knob on the base of the upper mandible, and a sort of wattle under the throat; a white line or fillet runs over the front of the brow, and a black stripe down the hinder part of the neck; the base of the bill is orange; the front of the neck and breast are yellowish-brown; the back, and all the upper parts, darkish-gray; the sides gray edged with white; belly white; and legs orange. It is variously called the Chinese, Spanish, Guinea, Cape, and Swan Goose; and is said to have been originally found only in Guinea, though it is now tolerably common, in a wild as well as in a domesticated state, both in warm and in cold climates. They are more noisy than any other species: nothing can stir by night or day without their sounding the alarm by their hoarse cacklings and shrill cries. They breed with the common Goose, and their offspring are as prolific as others.

THE BEAN GOOSE (*Anser segetum*) is a native of the Arctic regions, migrating periodically towards the southern parts of Europe. They arrive in the fens of England in the autumn, sometimes in large flocks, and leave us in April and May for the north; some retiring no farther to breed than the Hebrides. They resort equally to the corn fields and the fens, and are said to show a preference for the green corn as food. The head and top of the neck, back, and wing-coverts are ashy-brown; the base of the neck and under parts of the plumage are bright ash-colour; the rump is nearly black; the vent and under part of the tail are pure white; and the legs are reddish-orange. They lay ten or twelve white eggs, in a nest placed in the marshes, or among the heath.

GORGONIA: GORGONIADÆ. A genus and family of Zoophytes, described in Dr. Johnston's excellent work on the British Zoophytes as "polype-mass rooted, arborescent, consisting of a central axis barked with a polypiferous crust; the crust when recent soft and fleshy, when dried porous and friable." The species here figured (*Gorgonia verrucosa*) is somewhat fan-shaped, much and irregularly branched, the branches cylindrical, flexuous, and barked when dry with a white warted crust. It is found in

deep water, and is abundant along the whole of the south coast of England. "The polype-mass is more than twelve inches in height, and fifteen or seventeen in breadth, fixed to rocks by a broad circular fibro-corneous disc, shrub-like, branched from near the

WARTY GORGONIA.—(*GORGONIA VERRUCOSA*)

base, the branches expanded laterally, sometimes bushy, cylindrical, erect or erectopatent, warted. Axis black, smooth, and somewhat glossy, round or a little compressed, compact and corneous, with a snow-white pith in the centre, irregularly cellular and very like the pith of a rush. Crust, in dried specimens, white, cretaceous, friable, warted, with numerous polype-cells and wrinkled in the small spaces between them." Professor E. Forbes, alluding to another species (*Gorgonia flabellum*), which it was supposed had been admitted into the British Fauna on insufficient evidence, says, "The fisherman who brought it described it as being covered with living flesh when taken. On examination we found that it presented the curious appearance of West Indian incrusting shells and British mixed, and the living flesh was doubtless a British sponge, which had grown round the branches in many parts."

GORILLA. [See SUPPLEMENT.]

GOSHAWK. (*Falco palumbarius*.) The Goshawk is twenty-one inches in length; the bill and cere are blue; crown, black, bordered on each side by a line of white, finely speckled with black; upper parts, slate, tinged with brown; legs feathered half way down, and, with the feet, yellow; the breast and belly white, with a number of wavy lines or bars of black; the tail long, of an ash-colour, and crossed with four or five dusky bars; wings much shorter than the tail. The Goshawk frequents the deep solitudes of forests, preying upon hares, squirrels, and the larger ground birds; it also feeds on mice and small birds, and eagerly devours raw flesh. It plucks the birds very nimbly, and tears them into pieces before it eats them, but swallows the pieces entire. It is extremely destructive to game, darting through the woods after its prey with great

impetuosity : but if the object of its pursuit eludes its first attack, it almost immediately desists, and perches on some bough till 'new game presents itself. The Goshawk is now rare in the British islands, being chiefly restricted to the Highlands of Scotland ; but it is more abundant in the forest districts of continental Europe, and extends also through the temperate regions of Asia and America. It was formerly used in Europe, in common with the Falcon, Jerfalcon, &c. in the once celebrated royal pastime of falconry ; and it is said to be still used by the emperor of China, in his hunting excursions, when he is usually attended by his grand falconer, and a thousand of inferior rank. Wilson described the American bird under the name of *F. atricapillus*, but at the same time suspected that it might prove identical with the European, which has since been confirmed.

GRACKLE. (*Gracula*.) The principal species of this genus of birds are natives of Asia and America ; and they chiefly subsist on insects and fruits.

The **INDIAN GRACKLE.** (*Gracula religiosa*.) Edwards describes two varieties of this species, which resemble each other in every respect except in size ; the one being as large as a Magpie, and the other no larger than a Blackbird. They have round plump bodies, short tails, and legs of moderate length ; the head, neck, whole body, wings, and tail, are covered with glossy black feathers, shining in different lights with green, blue, and purple tints : a white spot appears in the middle of the wing ; and the legs and feet are of a deep yellow colour. These birds are found in different parts of India and the Indian islands : they are lively, docile, and learn to speak with as much facility as most of the Parrot tribe.

The **CRESTED GRACKLE** (*Gracula cristatella*) is of a black colour, inclining to a dusky blue ; but the bottoms of some of the first quills are white, which forms a white spot in each wing : though the tail is black, the side feathers are tipped with white : but it is chiefly distinguished for having on the forehead, just at the basis of the bill, a remarkable tuft of feathers, which it can erect at pleasure in form of a crest. It is a native of China.

The **PARADISE GRACKLE.** (*Gracula tristis*.) This species is rather longer than the Blackbird ; its colour chestnut brown, the head and neck black, but the latter tinged with gray : the plumes on the fore part of the head are fine and narrow, and behind each eye is a triangular bare space of a red colour : the abdomen is white ; the tail dark brown, the lateral feathers tipped with white ; the larger quill-feathers dusky, with white bases, forming an oblong white spot on the upper edge of each wing : the bill and legs are yellow. This bird is a native of India and the Philippine islands. It is very voracious, and particularly fond of locusts and grasshoppers ; relative to which Buffon relates the following curious anecdote :—The isle of Bourbon, where these birds were unknown, was overrun with

locusts, which had unfortunately been introduced from Madagascar ; their eggs having been imported in the soil with some plants which were brought from that island. In consequence of this, the Governor-general and the Intendant deliberated seriously on the means of extirpating the noxious insects ; and for that purpose caused several pair of the Indian Paradise Grackle to be introduced into the island. This plan promised to succeed ; but unfortunately some of the colonists, observing the birds eagerly thrusting their bills into the earth of the new-sown fields, imagined that they were in quest of the grain, and reported that the birds, instead of proving beneficial, would, on the contrary, be highly detrimental to the country. The cause was considered in form. On the part of the birds it was argued, that they raked in the new-ploughed grounds not for the sake of the grain, but the insects ; and were therefore beneficial. They were, however, proscribed by the council ; and in the space of two hours after the sentence was pronounced against them, not a Grackle was to be found in the island. This prompt execution was however followed by a speedy repentance : the locusts gained the ascendancy, and the people, who only viewed the present, regretted the loss of the Paradise Grackles. In a few years afterwards a few pair were again introduced : their preservation and breeding were made a state affair : the laws held out protection to them, and the physicians on their part declared their flesh to be unwholesome : the Grackles accordingly multiplied, and the locusts were destroyed. — The reader will find, under the word "Rook," this really important subject discussed at some length, in reference to the habits of that well-known insectivorous and granivorous bird.

GRALLÆ. The fourth order of the class *Aves*, comprehending the long-legged wading birds.

GRALLATORES. The fourth order of Birds according to the system of Mr. Vigors, being placed between the *Rasores* and the *Natatores*.

GRAMPUS. (*Delphinus orca*.) A cetaceous animal, from twenty to twenty-five feet long, and of such an extremely fierce and predaceous nature, that it not only destroys the porpoise and dolphin, but it is reported that it will even attack whales. The nose is flat, and reverted at the extremity ; and it has thirty teeth in each jaw, those in front being blunt, round, and slender ; the hinder sharp and thick ; and between each there is a space adapted to receive the teeth of the opposite jaw when the mouth is closed. The body is broad and deep ; the back is black, but on each shoulder there is a large white spot ; the sides are marbled with black and white ; and the belly is perfectly white. The back fin sometimes measures not less than six feet in length from the base to the tip. The Grampus is found in the Mediterranean and Atlantic seas, as well as in both the polar

regions; and it occasionally appears on the British coasts.

GRASS-FINCH. A genus of Passerine birds. [See POEPHILA.]

GRASSHOPPER. (*Acrydium*.) This genus of Orthopterous insects is distinguished from the Crickets by the roof-like position of the wing-covers, which in the crickets fold horizontally; and they are distinguished from the Locusts, by the inferior robustness of the body, and the length and slenderness of the legs and antennæ. There are several varieties, but it will be sufficient to give an account of the little Grasshopper that breeds in our meadows, and prolongs its shrill music through the summer, in order to elucidate the history of all.

The general colour of the Grasshopper is green, with a line of brown which streaks the back, and two pale lines under the belly and behind the legs. It may be divided into the head, the corselet, and the abdomen: the head is oblong, prone, and may be likened in shape to that of a horse; the month is covered by a kind of buckler, and armed with brownish hooked teeth; the antennæ are long and pointed; and the eyes are black and prominent. The corselet is elevated, narrow, and armed above and below with two serrated spines; the back is covered with a strong buckler, to which the muscles of the legs are firmly bonded, and round these muscles the vessels of respiration are seen; the last pair of legs are much longer and stronger than the first two pair, and have muscles extremely well adapted for leaping. There are four wings; the anterior ones springing from the second pair of legs, the posterior from the third pair: the hinder wings are much finer and more expansive than the foremost, and are therefore the principal instruments of flight. The abdomen, which is large, is composed of eight rings, and terminated by a forked tail covered with a kind of down. Towards the latter end of autumn the female is observed to be greatly distended with eggs, and she prepares to deposit her burden. In order to form a proper lodgment for them in the earth, Nature has provided her with an instrument at the end of her body, which she can sheathe and unsheathe at pleasure: with this she pierces the earth to the greatest depths possible; and into the opening thereby made she drops her eggs one after another. Having thus provided for the continuance of her race, she does not long survive: for, as the winter approaches, she gradually withers, and dies through a total decay. In the mean time the deposited eggs continue unaltered, either by the severity of the season or the delay of spring: they are oval, white, and of a horny consistence, and they contain a viscous transparent fluid. When the vernal sun begins to animate all nature, the eggs feel his benign influence; and, generally in the beginning of May, an insect is produced from each about the size of a flea: these are at first of a whitish colour, but at the end of two or three days they turn black; and, soon after, to a reddish brown; from their very origin they

exhibit the appearance of Grasshoppers without wings, and hop among the grass, as soon as excluded, with surprising agility. Having continued above twenty days from its exclusion without the use of its wings, which are folded up in its body, at length it prepares for its emancipation; and, in order to make the necessary dispositions for its approaching change, it ceases from its grassy food, and finds some convenient shelter where it may be protected from a passing shower. It then exhibits the same laborious writhings, heavings, and palpitations, which are perceptible in all other insects during their metamorphosis; it struggles hard, in fact, to free itself from prison. At length, the skin which covers the head and breast is observed to divide above the neck; and ere long the little insect extricates itself totally from the old skin, which it leaves adhering to the plant under which the transformation was performed. The Grasshopper, thus disengaged from its exterior skin, appears in its perfect form; but at this period it is extremely feeble, and its body quite soft. It is now of a greenish white colour, which becomes more vivid as the moisture on the surface dries up. Still, however, the insect discovers no signs of life, but appears quite spent, and overcome with its exertions. During this time the body continues drying, and the wings unfolding to their greatest expansion; and a curious observer may perceive them, fold after fold, opening to the sun, till at last they become longer than the two hinder legs: the body of the insect is also lengthened during this operation, and becomes more beautiful than before. These insects are generally vocal in the middle of summer; and, about sunset, their notes are much louder than during the heat of the day. The musical organs of the male consist of what has been termed a pair of taborets. They are formed by a thin and transparent membrane stretched in a strong half-oval frame in the triangular overlapping portion of each wing-cover. During the daytime these insects are silent, and conceal themselves among the leaves of trees; but at night they quit their lurking-places, and the joyous males begin the tell-tale call with which they enliven their silent mates. This proceeds from the friction of the taboret frames against each other when the wing-covers are opened and shut, and consists of two or three distinct notes almost exactly resembling articulated sounds, and corresponding with the number of times that the wing-covers are opened and shut; and the notes are repeated, at intervals of a few minutes, for hours together. Though averse to the exertions of flight, and slow in their aerial excursions, particularly when the weather is moist or cool, they are sometimes seen to fly to considerable distances. When roughly handled they bite sharply; and, in the act of flying, they make a particular noise with their wings. [See LOCUST.]

GRAYLING. (*Thymallus vulgaris*.) A fresh-water fish, of the *Salmonidae* family, in many respects very similar in its habits to the Trout, delighting in clear rapid streams,

and swimming with rapidity. Its figure is elegant, the body, which is longer and flatter than that of the Trout, seldom exceeds eighteen inches: the head is small and pointed, flattened at the top; teeth numerous, small, and incurved; behind the head, the nape and neck rise suddenly; the body deepest at the commencement of the dorsal fin, then tapering off to the tail; the back and sides are a fine silvery gray, but when the fish is just caught they are slightly varied with blue, green, and gold, with a few decided dark spots. The lateral line is straight; the scales are large, their lower edges being dusky, and forming regular rows from head to tail: the top of the back fin is red, the lower part being of a purple hue; the ventral fins

GRAYLING.—(THYMALLUS VULGARIS.)

are bluish, spotted with black; and the tail is considerably forked. The lips are rough; the tongue is smooth; and the gills are quadric. It is tolerably abundant in several rivers in the north, and also in the north-western counties of Hampshire and Wiltshire, where it is found in the Test and both the Avons. It is known to be plentiful in Sweden, Norway, and Lapland; and it may be generally remarked that it thrives best in rivers with rocky or gravelly bottoms, where stream and pool alternate. The spawning season is in April or May, therein differing from most of the other *Salmonidae*, which generally spawn late in the autumn: whereas the Grayling is in the finest condition in October and November, when Trout are out of season.

GREBE. (*Podiceps*.) The name given to a natural group of Water birds, allied to the *Divers*. Their distinguishing characters are—a long, straight, and sharp pointed bill; no tail; the toes flattened, separate, but broadly fringed at their edges by a firm membrane. This division of the webbed foot probably assists its action, in waters where there are many aquatic plants. The quickness with which they dive is very remarkable: their progression on land, however, is extremely awkward; for they are obliged to lie upon the whole length of the body, and then to shuffle along like seals, by the action of their feet against the ground. Their flight is very feeble; but in the act of diving, their wings are of great assistance to them.

The GREAT-CRESTED GREBE. (*Podiceps cristatus*.) The length of this bird is about twenty-one inches, and the expansion of its wings thirty. The bill is red at the base and black at the point, and between the bill and the eyes there is a stripe of black naked skin; the irides are pale red, and the head is adorned with a large dusky crest, divided in the middle. The cheeks and throat are surrounded with a long pendent

ruff of a bright tawny colour edged with black; the chin is white; the hind part of the neck and the back are of a sooty hue; and the rump is covered with long soft down, which supplies the place of a tail. The covert-feathers on the second and third joints of the wings and the secondaries are white; all the other wing-feathers are dusky: the breast and belly are of a silvery white colour, soft and glossy; the plumage under the wings is dusky; the outsides of the legs are also dusky, but the insides and the toes are a pale green. This bird is found on almost every lake in the north of Europe, and is common in marshes and meres in many parts of England; it breeds among reeds and flags, in a floating nest kept steady by the weeds of the margin; preys on fish; and very rarely quits its watery abode, where by diving and swimming, it is taught to expect food and security. The Grebe is mostly valued for the plumage of its breast, the flesh being rank and nauseous.

The other species of Grebes are the **EARED GREBE** (*Podiceps auritus*); the **RED-NECKED GREBE** (*Podiceps rubricollis*); and the **LITTLE GREBE** (*Podiceps minor*).

GREENFINCH. (*Chlorospiza chloris*.) This bird, which is also known as the Green Linnet and Green Grosbeak, is rather larger than a Sparrow: the beak is thick and whitish: head and back yellowish green; the edges of the feathers grayish inclining to ash-colour about the sides of the head and neck: rump and breast more yellow; greater quills yellow on the outer webs: tail slightly forked; the middle feathers dusky, and the four outer feathers on each side yellow on their exterior webs: legs flesh-colour. Female less bright, and with a brown cast. The Greenfinch is one of the most common birds in this country: it builds its nest in a low and thick bush or hedge, of hay, stubble, grass, and moss, lined with hair, wool, and feathers; laying four or five eggs of a pale green colour, sprinkled with small reddish spots, which are thickest at the larger ends. Its food is principally seed and grain; and it is very easily tamed. Though Greenfinches are frequently caged, their note is not to be much admired; but some, if brought up from the nest, will learn to imitate the songs of most other birds. In the winter this bird flocks with the Chaffinches and Yellowhammers; and migrates into warmer districts if the weather be very severe.

GREYHOUND. (*Canis [familiaris] gratus*.) This elegant variety of the hound is of no modern origin; for the sport of coursing the hare with Greyhounds was well known in Gaul in the fifth century; and in the annals of our own country it is recorded that among the dogs kept by royal sportsmen of the olden time, this was one; nay, by the forest laws of King Canute it was enacted, that no one under the degree of a gentleman should presume to keep a greyhound; and even he could keep it only if he lived more than two miles beyond a royal forest, unless two of the dog's toes were cut off. "The third Edward," as Mr. Bell writes, "who usually held his Court at Greenwich during

the hunting season, in order to be contiguous to his royal forest in Essex, kept his Greyhounds, with his other dogs, in what has from that circumstance been called the Isle of Dogs. In this instance, as in more ancient times, the game coursed by the Greyhounds was principally the Red Deer and the Fallow Deer; and it is clear that the dogs must necessarily have been of a very powerful breed to have pulled down so large and active an animal." The Greyhound is remarkable for the slenderness of its shape, the length and pointed form of its muzzle, and the extreme swiftness of its course; it hunts by sight, and not by scent, the nose

GREYHOUND —(CANIS [FAMILIARIS], GRAYUS.)

being far from keen; the ears droop at the points, and the eyes are small; the back is broad and muscular; the body is lank, and very much contracted beneath; the limbs combine length with muscular power; the neck is long, the chest is capacious and deep; and the tail is very slender, and curved upwards.—The ITALIAN GREYHOUND is a small and very beautiful variety of the species above described; but in this country it could be but of little value for any kind of hunting, as it is unable to bear even a very moderate degree of cold, and its delicate limbs are unequal to the labour of hard running.—The IRISH GREYHOUND, on the contrary, originally called the Wolf-dog, from its having been used in hunting the Wolf when that animal infested the forests of Ireland, is a large and powerful animal; indicating a considerable approach to the Greyhound in form, and supposed to be a cross of that species with the great Danish Dog.

GRIFFIN. (*Gryffetes*.) A genus of Accipitrine birds, which, though placed by Gmelin in his genus *Falco*, seem more nearly allied in their habits and conformation to the Vultures. [See GYPAETUS.]

GROSBEAK. (*Coccothraustidae* and *Ploceidae*.) There are a great variety of birds belonging to this genus; and their general appearance is very similar to birds of the Finch kind. They are distinguished by a strong and thick bill, by means of which they are enabled to break the stones of cherries and other fruit with the greatest facility. In general they are a shy, solitary race, chiefly residing at a distance from the abodes of man; and very few of them are calculated to add much to the harmony of the grove by their "dulcet warblings." Their feet have three toes before and one

behind; and their food generally consists of fruits and seeds. Some of the principal species are hereunder described.

THE HAWFINCH GROSBEAK. (*Coccothraustes vulgaris*.) This bird is an inhabitant of the milder climates of Europe, visiting this country only occasionally in severe winters, and being nowhere very numerous. The bill is of a horn colour, conical, and prodigiously thick at the base; the space between the bill and the eye, and thence to the chin and throat, is black; the top of the head reddish chestnut; the cheeks somewhat paler, and the back part of the neck grayish ash: the back and smaller wing-coverts chestnut; the greater wing-coverts gray, in some almost white, forming a band across the wing; the quills are all black, excepting some of the secondaries nearest the body, which are brown; and the four outer quills seem as if clipped off at the ends: the breast and belly pale rusty, growing whiter towards the vent; the tail is black, the ends of the middle feathers excepted, which are gray; the outer ones are tipped with white; legs pale brown. These birds vary considerably; in some the head is wholly black: in others the whole upper part of the body is of that colour; while others have been met with entirely white, excepting the wings. The female greatly resembles the male, but her plumage is less vivid. These birds generally inhabit the woods during summer, and in winter resort near the hamlets and farms. The female builds her nest in trees, of small dry roots and grass, lined with wool, feathers, &c. The eggs are of a bluish-green colour, with brown spots.

THE PINE GROSBEAK (*Loxia enucleator*) is rather larger than the preceding, being nearly nine inches long. Beak dusky, very thick at the base, and hooked at the tip: head, neck, breast, and rump, rose-coloured crimson; back and lesser wing-coverts black; greater wing-coverts tipped with white, forming two bars on the wing; quills and secondaries black, the latter edged with white; belly and vent straw-coloured. This bird is common in various parts of America, but is found only in this island in the pine forests of Scotland, where it is supposed to breed; its more native habitations are the pine forests of Siberia, Lapland, and the north of Russia. They build on trees, at a small distance from the ground, and there are generally four white eggs, which are hatched early in June.

THE GRENADIER GROSBEAK. (*Pyromelana orix*.) This species is gregarious, and builds its nest in large societies, among the reeds, near the rivers and ponds in the vicinity of the Cape of Good Hope. The brilliant plumage of these birds is described as being very striking. The forehead, sides of the head, chin, breast, and belly, are black; wings brown, with pale edges; the rest of the body a most beautiful red; lower part of the thighs brown; legs pale. In size the Grenadier Grosbeak may be compared with the house-sparrow.

THE CARDINAL GROSBEEK. (*Cardinalis Virginianus*; *Loxia cardinalis* of Linnæus.) This species, which is sometimes called the Cardinal-bird, is eight inches in length. The general plumage is a fine red: the bill pale red, and stout; on the head is a crest; and round the bill, and on the

CARDINAL GROSBEEK
(*CARDINALIS VIRGINIANUS*.)

throat, the colour is black; the quill and tail feathers is not of so bright a red as the body. The song of the Cardinal Grosbeak very much resembles that of the nightingale, and during the spring and summer its sweet notes are heard from the tops of the highest trees. It is met with in several parts of North America: and is said to collect together great quantities of maize and buckwheat, of which it is very fond.

THE BLUE GROSBEEK (*Guiraca caerulea*) is about six inches in length; the bill strong, thick at the base, sharp-pointed, and of a lead colour; surrounded at the base with black feathers: quills and tail brown, with a mixture of green; wing coverts with a red band; all the rest of the plumage blue: legs dusky. It is sometimes found entirely blue, except a black spot between the beak and eye. This species is a native of Brazil.

We might give many more specimens of the Grosbeak genus, if the descriptions were likely to afford matter of an interesting character; and we may also observe that the most important species will be found under other well-known names, as the Boli-finch, Greenfinch, &c. But there is one, called the Sociable Grosbeak, whose habits are worthy of particular notice; and with this species we shall conclude:—

THE SOCIABLE GROSBEEK. (*Philetærus socius*.) This bird, which is about the size of a Bullfinch, and whose prevailing colour is a rufous brown, inhabits the interior country in the Cape of Good Hope, where it was first discovered by Mr. Paterson, who gives the following history of it. "Few species of birds live together in such large societies, or have such an extraordinary mode of nidification as these: they build their nests on the Mimosa trees, which grow to a very large size, and appear to be well calculated for the purpose, as the smoothness of their

trunks prevents the birds from being attacked by monkeys and other noxious animals. The method in which their nests are made is very curious. On one tree there could not be less than from eight hundred to a thousand under one general roof. I call it a roof, because it resembles that of a thatched house, and projects over the entrance of the nest below in a very singular manner. The industry of these birds seems almost equal to that of the bee. Throughout the day they appear to be busily employed in carrying a fine species of grass, which is the principal material they employ for the purpose of erecting this extraordinary work, as well as for additions and repairs. Though my short stay in the country was not sufficient to satisfy me by ocular proof that they added to their nest as they annually increased in numbers; still, from the many trees which I have seen borne down by the weight, and others which I have observed with their boughs completely covered over, it would appear that this is really the case. When the tree, which is the support of this aerial city, is obliged to give way to the increase of weight, it is obvious that they are no longer protected, and are under the necessity of rebuilding in other trees. One of these deserted nests I had the curiosity to break down to inform myself of the internal structure of it: and found it equally ingenious with the external. There are many entrances, each of which forms a regular street, with nests on both sides, at about two inches distance from each other. The grass with which they build is called the Bushman's-grass; and I believe the seed of it to be their principal food; though, on examining their nests, I found the wings and legs of different insects. From every appearance the nest which I dissected had been inhabited for many years, and some parts of it were much more complete than others. This, therefore, I conceive to amount nearly to a proof that the animals added to it at different times, as they found necessary from the increase of the family, or rather of the nation or community."

GROUND PIG. (*Aulacodus Swinderianus*.) The name of a South African Rodent belonging to the sub-family *Echimyina*: it gets its name from its burrowing habits.

GROUND SQUIRREL. (*Tomias*.) A genus of Rodent mammalia allied to the true Squirrels, but distinguished from them by the possession of cheek-pouches, and their habit of retreating into subterraneous holes.

THE STRIPED GROUND SQUIRREL (*Tomias striatus*) is a very small species, inhabiting the vicinity of the Rocky Mountains. The general colour is reddish above, mixed with black, and whitish beneath, with four broad white lines on the back. It has not been observed to ascend trees, but nestles in holes, or on the edges of rocks; and the nest is composed of a most extraordinary quantity of vegetable substances. Its principal food seems to consist of the seeds of the pine.

LISTER'S GROUND SQUIRREL (*Tamias Listeri*) makes a burrow, generally, about

the roots of trees, or along fences and walls, often of considerable extent, and having several branches, and always two openings. On the back are five longitudinal black bands, separated on each side by two white ones. It is a very pretty, lively, and familiar animal, well known in the United States. A closely allied species is said to be extremely common in Siberia, inhabiting the maple and birch woods of that country, and generally forming their nests or burrows near the root of some tree: they are never known to ascend trees in the manner of other Squirrels, unless suddenly surprised or pursued, when they climb with great expedition, and conceal themselves among the branches: they collect their stores during the autumnal season, and on the setting in of winter conceal themselves in their burrows, the entrances of which they stop, and pass the greatest part of the rigorous season in sleep, and in feeding on their collected stores.

GROUSE. Under this general name are comprehended several species of birds classed by Linnaeus in the genus *Tetrao*. Their distinguishing characters are, that they have short arched bills; that their exterior and interior toes are connected to the first joint of the middle toe by a small membrane; that their legs are feathered down to the feet; and that they have a broad naked red skin over each eye.

The **Woon Grouse**, called also the **Cock of the Wood**, and in Scotland **CAPERCAILLIE**, (*Tetrao urogallus*) is a magnificent species, two feet nine inches in length, nearly four feet in extended breadth, and weighs from eight to fourteen pounds. The bill is very strong, convex, and of a light horn colour; over each eye there is a naked skin, of a bright red; irides hazel; the nostrils small, and almost hid under a covering of short dusky feathers, which extend under the throat, and are there much longer and darker than the rest: the head and neck are elegantly marked with small transverse lines of black and gray, as are also the back and wings, but more irregularly. The upper part of the breast is of a rich glossy green hue; the rest of the breast and belly are black, mixed with a few white feathers: the sides are marked like the neck; the coverts of the wings are crossed with undulated lines of black and reddish brown; the exterior webs of the greater quill feathers are black; the bend of the wing and under tail coverts pure white: the tail consists of eighteen feathers, and is rounded in shape, and black, with a small white spot on the outer feather on each side, near the extremity: the legs are very stout, and covered with brown silky feathers, with loose webs; the feet and claws horn colour, and the toes furnished on each side with a strong pectinated membrane. The female is considerably less than the male, and differs from him greatly in her colours: her throat is red; the transverse bars on the head, neck, and back are red and black; the breast reddish, varied with a few white spots; belly barred with orange and black, the top of each feather white;

the back and wings mottled with reddish brown and black; the scapulars tipped with white: the tail is of a deep rust colour, barred with black, and tipped with white.

This fine bird inhabits wooded and mountainous countries, particularly pine forests or plantations of juniper. In Russia, Sweden, and other northern countries, it is very common in the forests of pine, which there abound; and the cones of the fir trees, which it eats, as well as various plants and berries, at some seasons give an unpleasant flavour to its flesh. It was formerly met with in Ireland, the Highlands of Scotland, and parts of North Wales; but it is now very rarely indeed seen in these islands. Early in the spring the season for pairing commences: during this period the cock places himself on an eminence, where he displays a variety of attitudes, appearing unconscious of danger, and insensible to all around him: the feathers on his head stand erect, his neck swells, his tail is expanded, and his wings droop; his eyes sparkle, and the scarlet patch on each side of his head assumes a deeper dye; he at the same time utters his singular cry, which has been compared to the sound produced by the whetting of a scythe: it may be heard at a considerable distance, and never fails to draw to him his faithful mate. The female lays from eight to sixteen eggs, which are white, irregularly spotted with yellow, and larger than those of the common hen: they are generally placed in a dry situation, in an artless nest upon the ground, composed of heath tops; but she covers her eggs carefully with leaves when she is under the necessity of leaving them in search of food. As soon as the young are hatched they follow the mother, who leads them to procure the pupæ of ants and wild mountain berries, which are their first food.

BLACK GROUSE; BLACK GAME; HEATH-COCK, or BLACK COCK. (*Tetrao tetrix*.) The male bird is about two feet in length, and the expansion of his wings two feet

BLACK GROUSE.—(TETRAO TETRIX.)

nine. The prevailing colour of his plumage is black, richly glossed with blue on the

neck, back, and rump; the rest of the body being dull black. The bill is dark; the eyes deep blue; below each eye is a spot of dirty white, and eyebrows formed of a naked space of bright scarlet. The lesser wing-coverts are dusky brown; the greater white, which extends to the ridge of the wing, forming a spot of that colour on the shoulder when the wing is closed; the quills are brown, the lower parts and tips of the secondaries white, forming a bar of white across the wing: the tail is black, changing to deep violet, and when spread out, the feathers form a curve on each side; the under tail-coverts are pure white: the legs and thighs dark brown, mottled with white; the feet brown. Like the former species, these birds are common in Russia, Siberia, and other northern countries, chiefly in wooded and mountainous situations; and in the northern parts of our own island on uncultivated moors. The female is about one third less than the male; her tail is much less forked, and she differs from him considerably in colour; the head, neck, and breast being striped transversely with red and black; the back, wing-coverts, and rump deep red, varied with black lines; and the tail feathers black, with oblique zigzag red stripes, and tipped with white. The males are polygamous, and fight desperately with each other for the females. It is said that when the vanquished are put to flight, and the victors are left in possession of the field, they place themselves on an eminence, clap their wings, and with loud cries give notice to their females, who immediately resort to the spot. The hen makes an artless nest on the heathy ground, and usually lays from six to ten eggs, of a dirty white colour, blotched with spots of rusty brown. The young follow the hen for some time, but quit her at the commencement of the winter, and keep together in flocks of seven or eight till the spring. Their food consists principally of fruits and berries, and in winter, of the tops of the heath and birch; but, though they are particularly fond of wild and mountainous places, in summer they frequently come down from their lofty situations for the sake of feeding on corn.

The **RUFEN GROUSE** (*Bonasia umbellus*) is thus described in Wilson's American Ornithology:—"This elegant species is well known in almost every quarter of the United States, and appears to inhabit a very extensive range of country. It is common at Moose Fort, on Hudson's Bay, in lat. 61°; is frequent in the upper parts of Georgia; very abundant in Kentucky and the Indiana territory; and was found by Captains Lewis and Clarke in crossing the great range of mountains that divide the waters of the Columbia and Missouri, more than three thousand miles, by their measurement, from the mouth of the latter. Its favourite places of resort are high mountains, covered with the balsam pine, hemlock, and such like evergreens. Unlike the pinnated grouse, it always prefers the woods; is seldom or never found in open plains; but loves the pine sheltered declivities of mountains near streams of water. This great difference of

disposition in two species, whose food seems to be nearly the same, is very extraordinary. In those open plains called the Barrens of Kentucky, the pinnated grouse was seen in great numbers, but none of the ruffed; while in the high groves with which that singular

RUFFED GROUSE.—(*BONASIA UMBELLUS*.)

tract of country is interspersed, the latter, or pheasant, was frequently met with; but not a single individual of the former.

The native haunts of the pheasant being a cold, high, mountainous and woody country, it is natural to expect that, as we descend from thence to the sea shores, and the low, flat, and warm climate of the Southern States, these birds should become more rare; and such indeed is the case. In the lower parts of Carolina, Georgia, and Florida, they are very seldom observed: but, as we advance inland to the mountains, they again make their appearance. In the lower parts of New Jersey, we indeed occasionally meet with them; but this is owing to the more northerly situation of the country; for even here they are far less numerous than among the mountains.

"Dr. Turton, and several other English writers, have spoken of a long-tailed grouse, said to inhabit the back parts of Virginia, which can be no other than the present species, there being, as far as I am acquainted, only these two, the ruffed and pinnated grouse, found native within the United States.

"The manners of the pheasant are solitary; they are seldom found in coveys of more than four or five together, and more usually in pairs, or singly. They leave their sequestered haunts in the woods early in the morning, and seek the path or road, to pick up gravel, and glean among the droppings of the horses. In travelling among the mountains that bound the Susquehanna, I was always able to furnish myself with an abundant supply of these birds every morning without leaving the path. If the weather be foggy, or lowering, they are sure to be seen in such situations. They generally move along with great stateliness. The drumming, as it is usually called, of the pheasant, is another singularity of this species. This is performed by the male alone. In walking through solitary woods, frequented by these birds, a stranger is surprised by suddenly hearing a kind of thumping very similar to that produced by striking

two full-blown ox-bladders together, but much louder; the strokes at first are slow and distinct, but gradually increase in rapidity, till they run into each other, resembling the rumbling sound of very distant thunder, dying away gradually on the ear. After a few minutes' pause, this is again repeated, and, in a calm day, may be heard nearly half a mile off. This drumming is most common in spring, and is the call of the cock to his favourite female. It is produced in the following manner: The bird, standing on an old prostrate log, generally in a retired and sheltered situation, lowers his wings, erects his expanded tail, contracts his throat, elevates the two tufts of feathers on the neck, and inflates his whole body, something in the manner of the turkey cock, strutting and wheeling about with great stateliness. After a few manœuvres of this kind, he begins to strike with his stiffened wings in short and quick strokes, which become more and more rapid until they run into each other, as has been already described. This is most common in the morning and evening, though I have heard them drumming at all hours of the day. By means of this, the gunner is led to the place of his retreat; though, to those unacquainted with the sound, there is great deception in the supposed distance, it generally appearing to be much nearer than it really is.

"The pheasant begins to pair in April, and builds its nest early in May. This is placed on the ground, at the root of a bush, old log, or other sheltered and solitary situation, well surrounded with withered leaves. Unlike that of the quail, it is open above, and is usually composed of dry leaves and grass. The eggs are from nine to fifteen in number, of a brownish white, without any spots, and nearly as large as those of a pullet. The young leave the nest as soon as hatched, and are directed by the cluck of the mother, very much in the manner of the common hen. On being surprised, she exhibits all the distress and affectionate manœuvres of the quail, and of most other birds, to lead you away from the spot. I once started a hen pheasant with a single young one, seemingly only a few days old; there might have been more, but I observed only this one. The mother fluttered before me for a moment; but, suddenly darting towards the young one, seized it in her bill, and flew off along the surface through the woods, with great steadiness and rapidity, till she was beyond my sight, leaving me in great surprise at the incident. I made a very close and active search around the spot for the rest, but without success. Here was a striking instance of something more than what is termed blind instinct, in this remarkable deviation from her usual manœuvres when she has a numerous brood. It would have been impossible for me to have injured this affectionate mother, who had exhibited such an example of presence of mind, reason, and sound judgment, as must have convinced the most bigoted advocates of mere instinct. To carry off a whole brood in this manner at once would have been impossible, and to attempt to save one at the expense of the

rest would be unnatural. She therefore usually takes the only possible mode of saving them in that case, by decoying the person in pursuit of herself, by such a natural imitation of lameness as to impose on most people. But here, in the case of a single solitary young one, she instantly altered her plan, and adopted the most simple and effectual means for its preservation.

"The pheasant generally springs within a few yards, with a loud whirring noise, and flies with great vigour through the woods, beyond reach of view, before it alights. With a good dog, however, they are easily found; and at some times exhibit a singular degree of infatuation, by looking down from the branches where they sit, on the dog below, who, the more noise he keeps up, seems the more to confuse and stupify them, so that they may be shot down, one by one, till the whole are killed, without attempting to fly off. In such cases those on the lower limbs must be taken first; for, should the upper ones be first killed, in their fall they alarm those below, who immediately fly off. In deep snows they are usually taken in traps, commonly dead traps, supported by a figure & trigger. At this season, when suddenly alarmed, they frequently dive into the snow, particularly when it has newly fallen, and, coming out at a considerable distance, again take wing. They are pretty hard to kill, and will often carry off a large load to the distance of two hundred yards, and drop down dead. Sometimes, in the depth of winter, they approach the farm house, and lurk near the barn, or about the garden. They have also been often taken young, and tamed, so as to associate with the fowls; and their eggs have frequently been hatched under the common hen; but these rarely survive until full grown. They are exceedingly fond of the seeds of grapes; occasionally eat ants, chestnuts, blackberries, and various vegetables. Formerly they were numerous in the immediate vicinity of Philadelphia; but, as the woods were cleared and population increased, they retreated to the interior. At present there are very few to be found within several miles of the city, and those only singly, in the most solitary and retired woody recesses.

"The pheasant is in best order for the table in September and October. At this season they feed chiefly on whortleberries, and the little red aromatic partridge-berries; the last of which give their flesh a peculiar delicate flavour. With the former our mountains are literally covered from August to November; and these constitute, at that season, the greater part of their food. During the deep snows of winter, they have recourse to the buds of alder, and the tender buds of the laurel. I have frequently found their crops distended with a large handful of these latter alone; and it has been confidently asserted, that, after having fed for some time on the laurel buds, their flesh becomes highly dangerous to eat of, partaking of the poisonous qualities of the plant. The same has been asserted of the flesh of the deer, when, in severe weather and deep snows, they subsist on the leaves and bark of the laurel.

Though I have myself ate freely of the flesh of the pheasant, after emptying it of large quantities of laural buds, without experiencing any bad consequences, yet, from the respectability of those, some of them eminent physicians, who have particularized cases in which it has proved deleterious, and even fatal, I am inclined to believe, that, in certain cases, where this kind of food has been long continued, and the birds allowed to remain undrawn for several days, until the contents of the crop and stomach have had time to diffuse themselves through the flesh, as is too often the case, it may be unwholesome and even dangerous. Great numbers of these birds are brought to our markets, at all times, during fall and winter; some of which are brought from a distance of more than a hundred miles, and have been probably dead a week or two, unpicked and undrawn, before they are purchased for the table. Regulations, prohibiting them from being brought to market unless plucked and drawn, would, very probably, be a sufficient security from all danger. At these inclement seasons, however, they are generally lean and dry; and, indeed, at all times, their flesh is far inferior to that of the quail, or of the plumed grouse. They are usually sold, in Philadelphia market, at from three quarters of a dollar to a dollar and a quarter a pair, and sometimes higher.

"The pheasant, or partridge of New England, is eighteen inches long, and twenty-three inches in extent; bill, a horn colour, paler below; eye, reddish hazel, immediately above which is a small spot of hare skin, of a scarlet colour; crested; head and neck, variegated with black, red brown, white, and pale brown; sides of the neck furnished with a tuft of large black feathers, twenty-nine or thirty in number, which it occasionally raises; this tuft covers a large space of the neck destitute of feathers; body above, a bright rust colour, marked with oval spots of yellowish white, and sprinkled with black; wings, plain olive brown, exteriorly edged with white, spotted with olive; the tail is runding, extends five inches beyond the tips of the wings, is of a bright reddish brown, beautifully marked with numerous waving transverse bars of black, is also crossed by a broad band of black, within half an inch of the tip, which is bluish white, thickly sprinkled and speckled with black; body below, white, marked with large blotches of pale brown; the legs are covered half way to the feet with hairy down of a brownish white colour; legs and feet, pale ash; toes, pectinated along the sides; the two exterior ones joined at the base, as far as the first joint, by a membrane; vent, yellowish rust colour.

"The female, and young birds, differ in having the ruff or tufts of feathers on the neck of a dark brown colour; as well as the bar of black on the tail inclining much to the same tint."

RED GROUSE; MOOR COCK, or GORCOCK. (*Lagopus Scoticus*.) This species is much smaller than the Black Grouse, its length being only about fifteen inches, and its ex-

panded width twenty-six. The bill is black, and at its base is a white spot on each side; the throat is red; each eye is arched with a large naked spot, of a bright scarlet; the plumage on the head and neck is a light tawny red, each feather being marked with several transverse bars of black; the back and scapulars are a deeper red, and on the middle of each feather is a large black spot; the breast and belly are of a purplish hue, crossed with small dusky lines; the tail consists of sixteen feathers, of equal lengths, the four middlemost barred with red, the others black; the thighs are a pale red, obscurely barred with black; the legs and feet are clothed with soft white feathers down to the claws, which are strong, and of a light colour. This species seems to be peculiar to Britain; it is very plentiful in the Highlands of Scotland, and by no means scarce in any of the wild, heathy, and mountainous tracts in the northern counties of England and Wales. Red Grouse pair in spring, and lay from six to ten eggs; the young brood follows the hen during the whole summer; and, in winter, they unite in flocks of forty or fifty; they are sometimes seen in the valleys, but generally keep on the summits of hills, where they feed on mountain berries, &c., and are exceedingly shy and wild.

WHITE GROUSE. [See PTARMIGAN.]

"**LONG-TAILED GROUSE.** (*Tetrao Phasianellus*.) This bird, which is about the size of a pheasant, inhabits the mountainous parts of the country about Hudson's Bay, and other northern parts of the American continent. The bill is dusky, the head and neck are of a bright reddish brown, variegated with transverse waved dusky lines; the plumage of the back, wings, and tail is black in the middle, indented with bright brown on the sides, and transversely marked with black and brown at the tips; the outer coverts of the wings, and the quill feathers next the back, have white tips; and the primaries have spots of white along their outer webs. The two middle feathers of the tail are considerably the longest, the rest gradually shortening on each side; the upper part of the breast is brown, but by degrees becomes white; as do the belly, the sides under the wings, and the covert feathers under the tail. The legs are covered with fine filiform feathers of a pale brown colour, transversely variegated with dusky lines. They feed upon juniper berries and buds; associate in small flocks; and lay their eggs, which vary from ten to sixteen, in a nest on the ground, artlessly composed of grass, and lined with a few feathers: the eggs are white, and are hatched about the middle of June, the young immediately following the mother. The flesh of these birds is held in great estimation.

CANADA GROUSE. (*Tetrao Canadensis*.) This species, which is found in great abundance in the most northerly parts of America, is rather more than thirteen inches in length; the female two inches less. The upper parts of the head, neck, and body of the male bird are transversely barred with dusky

and gray brown; over the eyelids is a bare red space; nostrils covered with black, with a small white spot on each side, and one beneath; throat, breast, and belly, black; the latter spotted with white, except the middle: sides of the body barred transversely with grey-brown and dusky; the feathers with a white stripe near the tip: under tail coverts black and white: tail black, tipped with rufous: feathers of the tarsi gray-brown: claws gray: beak black.

PINNATED GROUSE. (*Tetrao Cupido.*) In its voice, manners, and peculiarity of plumage, the Pinnated Grouse is the most singular, and, in its flesh, the most excellent, of all those of its tribe that inhabit the territory of the United States. Though an inhabitant of different and very distant districts of North America, this rare bird is

PINNATED GROUSE — (*TETRAO CUPIDO.*)

extremely particular in selecting his place of residence, pitching only upon those tracts whose features and productions correspond with his modes of life, and avoiding immense intermediate regions that he never visits. Open dry plains, thinly interspersed with trees, or partially overgrown with shrub oak, are his favourite haunts: their predilection for such situations being, according to the opinion of Wilson, to be best accounted for by considering the following facts and circumstances:—First, their mode of flight is generally direct, and laborious, and ill calculated for the labyrinth of a high and thick forest, crowded and intersected with trunks and arms of trees, that require continual evolution of wing, or sudden turnings, to which they are by no means accustomed. Secondly, their known dislike of ponds, marshes, or watery places, which they avoid on all occasions, drinking but seldom, and it is believed, never from such places. The last, and probably the strongest inducement to their preferring these plains, is the small acorn of the shrub oak; the strawberries, huckleberries, and partridge-berries, with which they abound, and which constitute the principal part of the food of these birds. These brushy thickets also afford them excellent shelter, being almost impenetrable to dogs or birds of prey.

The Pinnated Grouse is nineteen inches long, twenty-seven inches in extent, and weighs about three pounds; the neck is furnished with supplemental wings, each composed of eighteen feathers, five of which are

black, and about three inches long; the rest shorter, also black, streaked laterally with brown, and of unequal lengths; the head is slightly crested; over the eye is an elegant semicircular comb of rich orange, which the bird has the power of raising or relaxing; under the neck wings are two loose, pendulous, and wrinkled skins, extending along the side of the neck for two-thirds of its length, each of which, when inflated with air, resembles, in bulk, colour, and surface, a middle-sized orange; chin, cream-coloured; under the eye runs a dark streak of brown; whole upper parts mottled transversely with black, reddish brown, and white; tail short, very much rounded, and of a plain brownish soot colour; throat elegantly marked with touches of reddish brown, white, and black; lower part of the breast and belly, pale brown, marked transversely with white; legs covered to the toes with hairy down of a dirty drab colour; feet dull yellow; toes pectinated; vent whitish; bill brownish horn colour; eye reddish hazel. The female is considerably less; of a lighter colour; destitute of the neck wings, the naked yellow skin on the neck, and the semicircular comb of yellow over the eye.

The season for pairing is in March, and the breeding time is continued through April and May. Then the male Grouse distinguishes himself by a peculiar sound. When he utters it, the parts about the throat are sensibly inflated and swelled. It may be heard on a still morning for three or more miles. This noise is a sort of ventriloquism. It does not strike the ear of a bystander with much force, but impresses him with the idea, though produced within a few rods of him, of a voice a mile or two distant. This note is highly characteristic. Though very peculiar, it is termed *tooting*, from its resemblance to the blowing of a conch or horn from a remote quarter. The female makes her nest on the ground, in recesses very rarely discovered by men; and she usually lays from ten to twelve brownish-coloured eggs, much resembling those of a guinea-hen. When hatched, the brood is protected by her alone. Surrounded by her young, the mother bird exceedingly resembles a domestic hen with her chickens. When at such times they are surprised, the dam utters a cry of alarm; and while the little ones are hurrying to a place of safety, their anxious parent beguiles the spectator by drooping and fluttering her wings, limping along the path, rolling over in the dirt, and other pretences of inability to walk or fly.

During the period of mating, and while the females are occupied in incubation, the males have a practice of assembling, principally by themselves. To some select and central spot where there is very little underwood, they repair from the adjoining district. From the exercises performed there, this is called a *scratching place*. The time of meeting is the break of day. As soon as the light appears, the company assembles from every side, sometimes to the number of forty or fifty. When the dawn is past, the ceremony begins by a low tooting from one

of the cocks. This is answered by another; and they presently come forth one by one from the bushes, strutting about with all the pride and ostentation they can display. Their necks are incurvated; the feathers on them are erected into a sort of ruff; the plumes of their tails are expanded like fans; they strut about in a style resembling the pomp of the turkey-cock. They seem to vie with each other in stateliness; and, as they pass each other, frequently cast looks of insult, and utter notes of defiance. These are the signals for battles. They engage with wonderful spirit and fierceness; and during their contests, they leap a foot or two from the ground, and utter a cackling, screaming, and discordant cry. These places of exhibition have been often discovered by the hunters; and a fatal discovery it has been for the poor Grouse. Their destroyers construct for themselves lurking holes made of pine branches, called "bough houses," within a few yards of the spot. Hither they repair with their fowling-pieces, in the latter part of the night, and wait the appearance of the birds. Watching the moment when two are proudly eyeing each other, or engaged in battle, or when a greater number can be seen in a range, they pour on them a destructive charge of shot. They commonly keep together in coveys of ten or a dozen, or packs, as the phrase is, until the pairing season; and it has been remarked, that when a company of sportsmen have surrounded a pack of Grouse, the birds seldom or never rise upon their pinions while they are encircled; but each runs along till it has passed the person that is nearest, and then flutters off with the utmost expedition.—The interesting facts contained in the foregoing account are derived from the inimitable "American Ornithology" by Alex. Wilson.

GRUB. A name applied more especially to the hexapod worms or maggots hatched from the eggs of beetles.

GRUIDÆ. The name of the family of wading birds represented by the Crane.

GRUS. A genus of Grallatorial birds belonging to the family *Gruidæ*. [See CRANE.]

GRYLLIDÆ. The second family belonging to the *Saltatoria Orthoptera*; containing the Field and House Cricket. [See CRICKET.]

GUACHARO BIRD. (*Steatornis Caripensis*.) A bird of South America, belonging to the family of Goatsuckers (*Coprimulgidae*), relative to the locality and habits of which a most interesting account is given by Baron Humboldt, in his "Personal Narrative." This bird is of the size of a common fowl; the plumage sombre, brownish-grey, mixed with small striae and black dots; large white heart-shaped spots bordered with black on the head, and on the wing and tail feathers; but no spots on the back: the bill is horny, wide, and long; the upper mandible hooked; and the base is furnished with stiff hairs, directed forwards.

The following narrative is derived, in a somewhat abridged form, from an article by the talented author of *Zoological Recreations*.—"When they (Humboldt and his party) arrived at the foot of the lofty mountain of Guacharo, they were only four hundred paces from the cavern, without yet perceiving the entrance. The torrent runs in a hollow excavated by the waters; and they went on under a ledge or cornice, the projection of which prevented them from seeing the sky. The path winds like the river, and, at the last turning, they suddenly stood before the immense opening of the cave. The *Cueva del Guacharo* is pierced in the vertical profile of a rock, and the entrance is towards the south, forming a vault eighty feet broad and seventy-two feet high, an elevation but a fifth less than that

GUACHARO.—(*STEATORNIS CARIPENSIS*.)

of the Louvre. The rock surmounting the cavern was covered with trees of gigantic height, and all the luxuriant profusion of an intertropical vegetation. The travellers saw with astonishment plantain-leaved heliconias eighteen feet in height, the praga palm, and tree arums, follow the banks of the river, even to the subterranean places. There the vegetation continues, as in the deep crevices of the Andes, half shut out from the light of day, nor does it disappear till a distance of thirty or forty paces from the entrance. The party went forward for about four hundred and thirty feet without being obliged to light their torches. Where the light began to fail, they heard from afar the hoarse cries of the *Guacharo birds*. These birds quit the cavern only at night-fall, especially when there is moonlight; and Humboldt remarks that it is almost the only frugivorous nocturnal bird yet known. It feeds on very hard fruits, and the Indians assured him that it does not pursue either the lamellicorn insects or those *phalænæ* which serve as food to the goatsuckers. He states that it is difficult to form an idea of the horrible noise made by thousands of these birds in the dark recesses of the cavern, whence their shrill and piercing cries strike upon the vaulted rocks, and are repeated by the echo in the depths of the grotto. By fixing torches of copal to the end of a long

pole, the Indians showed the nests of these birds fifty or sixty feet above the heads of the explorers, in funnel-shaped holes, with which the cavern roof is pierced like a sieve.

"Once a year, near midsummer, the Guacharo cavern is entered by the Indians. Armed with poles, they ransack the greater part of the nests, while the old birds hover over the heads of the robbers, as if to defend their brood, uttering horrible cries. The young which fall down are opened on the spot. The peritoneum is found loaded with fat, and a layer of the same substance reaches from the abdomen to the vent, forming a kind of cushion between the bird's legs. Humboldt here remarks, that this quantity of fat in frugivorous animals, not exposed to the light, and exerting but little muscular motion, brings to mind what has been long observed in the fattening of geese and oxen. It is well known, he adds, how favourable darkness and repose are to this process. At the period above mentioned, which is generally known at Caripe by the designation of 'the oil harvest,' huts are built by the Indians, with palm leaves, near the entrance, and even in the very porch of the cavern. There the fat of the young birds just killed is melted in clay pots over a brushwood fire; and this fat is named butter or oil of the Guacharo. It is half liquid, transparent, inodorous, and so pure that it will keep above a year without turning rancid. Humboldt observes that the race of Guacharo birds would have been extinct long since if several circumstances had not contributed to its preservation. The natives, withheld by superstitious fears, seldom dare to proceed far into the recesses of the cavern. Humboldt had great difficulty in persuading them to pass beyond the outer part of the cave, the only portion of it which they visit annually to collect the oil; and the whole authority of the *Padres* was necessary to make them penetrate as far as the spot where the floor rises abruptly at an inclination of sixty degrees, and where a small subterraneous cascade is formed by the torrent. In the minds of the Indians this cave, inhabited by nocturnal birds, is associated with mystic ideas, and they believe that in the deep recesses of the cavern the souls of their ancestors sojourn. They say that man should avoid places that are enlightened neither by the sun nor the moon; and 'to go and join the Guacharocs' means to rejoin their fathers—in short, to die. At the entrance of the cave the magicians and poisoners perform their exorcisms to conjure the chief of the evil spirits. It appears also, as another cause of preservation, that Guacharo birds inhabit neighbouring caverns too narrow to be accessible to man, and from these perhaps the great cavern is repopulated; for the missionaries declared that no sensible diminution of the birds had been observed. Young birds of this species have been sent to the port of Cumana, and have lived there several days, but without taking any food; the seeds offered to them not suiting them. The crops and gizzards of the young birds opened in the cavern contain all sorts of hard and dry fruits, which are conveyed to

them by their parents; these are preserved, and, under the name of *semilla del Guacharo* (Guacharo seed), are considered a celebrated remedy against intermittent fevers, and sent to the sick at Cariaco and other low localities where fever prevails. The *Cueva del Guacharo* is situated nearly in lat. $10^{\circ} 10'$, and consequently in the centre of the torrid zone."

GUAN. A genus of Gallinaceous birds found in the New World. [See FENELOR.]

GUANA. The name given to several species of Lizards (*Iguana*). The best known species (*Iguana tuberculata*) is found in many parts of America and the West Indian islands. It inhabits rocky and woody places; feeds on insects and vegetables; and is often seen of the length of from three to even five feet: its general colour is green, shaded with brown: the back is strongly serrated; and this, with its large gular pouch, which it has the power of inflating to a great degree, gives a formidable appearance to an animal otherwise harmless. We learn from Catesby that these reptiles are of various sizes, from two to five feet in length; that their mouths are furnished with exceeding small teeth, but their jaws are armed with a long beak, with which they bite with great strength; and that they inhabit warm countries only. Many of the Bahama islands abound with them, where they nestle in hollow rocks and trees. Their eggs have not a hard shell, like those of alligators, but a skin only, like those of a turtle; and are esteemed a good food: they lay a great number of eggs at a time, in the earth, which are there hatched by the sun's heat. These Guanas are a great part of the subsistence of the inhabitants of the Bahama islands, for which purpose they visit many of the remote *Kays* and islands in their sloops to catch them, which they do by dogs trained up for that purpose. Their flesh is easy of digestion, delicate, and well-tasted: they are sometimes roasted, but the more common way is to boil them, taking out the leaves of fat, which are melted and clarified, and put into a calabash or dish, into which they dip the flesh of the Guana as they eat it. Though they are not amphibious, they are said to keep under water above an hour. Their pace on land is slow; and when they swim, they do not use their feet, but merely guide themselves with their tails. They are so impatient of cold, that they rarely appear out of their holes but when the sun shines.

GUANACO. The local name of a variety of species of the Llama (which see).

GUDGEON. (*Cyprinus gobicus*.) A small Malacopecterygious fresh-water fish, generally about five or six inches in length and of a sub-cylindrical shape; its usual colour is a pale olive brown above, spotted with black; the sides silvery, and the belly white; the scales are small; the tail is forked; and both thint and the dorsal fin are spotted with black: the upper jaw is longer than the lower; and furnished with short eltri. Gudgeons appear to delight in slow rivers: they

swim together in shoals, feeding on worms, aquatic insects, &c., and affording excellent amusement to anglers from the avidity with

GUDGEON.—(GUPHUS OOHIO.)

which they seize the bait: they may also be taken in considerable numbers with the casting-net. The Gudgeon spawns in May, generally among stones in shallow water. The flesh is delicate, and easy of digestion.

GUILLEMOT. (Uria.) The Guillemots are a genus of sea-birds, having a striking resemblance both to the *Alcidæ* (Auks) and the *Colymbidæ* (Divers). Their bills, though of a slender shape, are firm, strong, and pointed; the upper mandible slightly bending near the end, and the base covered with soft short feathers: tongue long and slender; legs placed far backward; and no hind toe. Some of the species appear to be very stupid, frequent experience not seeming to teach them the danger of fire-arms; while others are sufficiently alert. They are numerously spread over various parts of the northern regions; and, like many others, seek more temperate climes on the approach of winter: thus during that season they are regular visitants of the British coasts.

FOOLISH GUILLEMOT.—(URIA TROILE.)

The FOOLISH GUILLEMOT. (Uria troile.) This bird is about seventeen inches in length, and twenty-seven in breadth. The bill is bluish-black, straight, nearly three inches long, and sharp-pointed: from each eye to the hinder part of the head there is a slight division of the plumage; and the feathers on the upper part of the bill are short, and soft as velvet. The head, neck, back, wings, and tail, are of a deep mouse-colour; the tips of the lesser quill-feathers, the breast, belly, and vent, are white; the entire under side of the body is pure white: legs dusky. Like the Auk, which it greatly resembles, the Guillemot lays but one egg, which is large in proportion to her size: sometimes it is of a pale blue or sea-green colour, and at other times white, spotted, or neatly

streaked with intersecting lines. These birds are found in great numbers on the cliffs which encircle several parts of our coasts; and, in the breeding season especially, they will often suffer themselves to be killed or taken, rather than quit the cliff they have chosen for their abode.

The young has been described as a distinct species, by some authors, as the *Lesser Guillemot*. In this state it measures sixteen inches in length, and from tip to tip of its extended wings, twenty-six. The top of the head, the whole upper part of the body, the wings, and the tail, are of a very dark mouse-colour; the cheeks, throat, and lower side of the body, white; from the angle of the eye is a dusky stroke, pointing to the back part of the head; the tips of the secondary feathers are white; the tail is very short; and the legs and feet are dusky.

The BLACK GUILLEMOT. (Uria grylle.) This species, called by seamen the *Dorekey* or *Dorekie*, differs from the preceding principally in the colour of its plumage, which, except a large patch of white on the coverts of each wing, is black, sleek and glossy; its feathers appearing all unwebbed, like silky hair: legs and feet red; claws black. The

BLACK GUILLEMOT.—(URIA GRYLLE.)

nest is made in the deep crevices of the rocks which overhang the sea: the egg (for it is generally said that one egg only is laid) is grey, sometimes spotted with rust-colour. On this much questioned and very questionable fact, the observing and intelligent American ornithologist, Audubon, thus writes:—"Whether European writers have spoken of this species at random, or after due observation, I cannot say. All I know is, that every one of them whose writings I have consulted, says that the Black Guillemot lays only one egg. As I have no reason whatever to doubt their assertion, I might be tempted to suppose that our species differs from theirs, were I not perfectly aware that birds in different places will construct different nests, and lay more or fewer eggs. Our species always deposits three, unless it may have been disturbed; and this fact I have assured myself of by having caught the birds in more than twenty instances sitting on that number. Nay, on several occasions, at Labrador, some of my party and myself saw several Black Guillemots sitting on eggs in the same fissure of a rock, where every bird had three eggs under it; a fact which I communicated to my friend Thomas Nuttall. What was most surprising

to me was, that even the fishermen there thought that this bird laid only a single egg; and when I asked them how they knew, they simply and good-naturedly answered that they had heard so."

BLACK GUILLEMOT—WINTER PLUMAGE.
(ORIA ORYLE)

We now turn to the first volume of Mr. Waterton's amusing and characteristic Essays, to extract his *Notes of a visit to the haunts of the Guillemot*. "The immense range of perpendicular rocks, lashed by old ocean's briny surge, offers a choice and favourable retreat to myriads of wild-fowl, from far-famed Flamborough-head to Bemp-ton, and thence to Buckton and Spenton, and outwards to the Bay of Filey. He who wishes to examine the nidification of these birds ought to be at this part of the sea-coast early in the month of May. About five miles from Bridlington Quay is the village of Flamborough, chiefly inhabited by fishermen; and a little farther on is a country inn, called the North Star, which has good accommodation for man and horse; but a lady would feel herself ill at ease in it, on account of the daily visits of the fishermen, those hardy sons of Neptune, who stop at it on their way to the ocean, and again on their return. Here they rendezvous, to fortify their interior with a pint or two of comfort, and to smoke a pipe, by way of compensation for the many huffs which they ever and anon receive in the exercise of their stormy and nocturnal calling.

"On the bare ledges of these stupendous cliffs the Guillemot lays its egg, which is exposed to the face of heaven, without any nest whatever: but the razor-hulls and puffins lay theirs in crannies, deep and difficult of access. Here too the peregrine falcon breeds, and here the raven rears its young; while the rock-pigeon and the starling enter the fissures of the precipice, and proceed with their nidification, far removed from the prying eye of man. The Kittiwake makes her nest of dried grass wherever she can find a lodgment, and lays two spotted eggs, very rarely three. The cormorant and shag inhabit that part of the rocks which is opposite to Buckton Hall. You are told that the cormorants had their nests, in former times, near to the Flamborough lighthouse; but now these birds totally abandon the place during the breeding season. The jackdaw is found throughout the whole of this bold and craggy shore: he associates with the sea-fowl, as though he were quite at home amongst his own inland congeners. Towards the top of the cliffs, both rabbits and foxes have descended from the table land above them, and managed to find a shelter

among the crevices, in places where you would suppose that no four-footed animal would ever dare to venture. A low mound, half earth, half stone, thrown up by the farmers for the protection of their flocks, skirts the winding summit of the precipice. Cattle have been known to surmount this artificial boundary, and lose their lives in the roaring surge below. This extensive range of rocks, as far as appertains to birds, is not considered private property. Any person who can climb it may carry away what number of eggs he chooses. Still there is a kind of honourable understanding betwixt the different sets of climbers, that they will not trespass over the boundaries which have been marked by mutual consent.

"The usual process of seeking for the eggs is generally carried on by three men, though two will suffice in case of necessity. Having provided themselves with two ropes of sufficient length and strength, they drive an iron bar into the ground, about six inches deep, on the table land at the top of the precipice. To this bar is fastened the thickest of the two ropes, and then it is thrown down the rocks. He who is to descend now puts his legs through a pair of hempen braces, which meet round his middle, and there form a waistband. At each end of this waistband is a loophole, through which they reeve the smaller rope. Sometimes an iron hook and eye are used in lieu of this loop. A man now holds the rope firmly in his hand, and gradually lowers his comrade down the precipice. While he is descending he has hold of the other rope, which was fastened to the iron bar; and, with this assistance, he passes from ledge to ledge, and from rock to rock, picking up the eggs of the Guillemot, and putting them into two bags, which he had slung across his shoulder ere he commenced his arduous undertaking. When he has filled these bags with eggs, he jerks the rope, and the motion informs his friend at the top that it is now time to draw him up. On coming up again to the place from whence he first set out, all the eggs are taken from the bags, and put into a large basket, prior to their being packed in hampers, and carried off in a cart by wholesale dealers, who purchase them from the climbers for sixpence the score. At Bridlington and the neighbouring places the eggs are retailed at a halfpenny a-piece. The rocks are searched for eggs every third day, provided the weather be fair. It requires considerable address on the part of the descending climber to save himself from being hit by fragments of the rock, which are broken off by the rope coming in contact with them. He avoids the danger by moving sideways when the stone is falling, and by taking care, as he goes down, to clear away with his foot any portion of the rock that seems ready to give way. One of the climbers, while he was imparting to me instructions how to act, grinned purposely, and showed his upper jaw. I learned by his story, that, last year, a falling stone had driven two of his front teeth down his throat; while the poor climber, with all his dexterity, was unable to fend off the blow.

"As I was lowered down, the grandeur and sublimity of the scene beggared all description, and amply repaid any little unpleasant sensations which arose on the score of danger. The sea was roaring at the base of this stupendous wall of rocks; thousands and tens of thousands of wild-fowl were in an instant on the wing: the kittiwakes and jackdaws rose in circling flight; while most of the Guillemots, razorbills, and puffins left the ledges of the rocks in a straight and downward line, with a peculiarly quick motion of the pinions, till they plunged into the ocean. It was easy to distinguish the puffins from the razorbills in their descent: these presented a hack of a uniformly dark colour, those had a faint white diagonal line running across the wings. The nests of the kittiwakes were close to each other, on every part of the rocks which was capable of holding them; and they were so numerous as totally to defy any attempt to count them. On the bare and level ledge of the rocks, often not more than six inches wide, lay the eggs of the Guillemots: some were placed parallel with the range of the shelf, others nearly so, and others with their blunt and sharp ends indiscriminately pointing to the sea. By no glutinous matter, nor any foreign body whatever, were they affixed to the rock: bare they lay, and unattached, as on the palm of your outstretched hand. You might see nine or ten, or sometimes twelve old Guillemots in a line, so near to each other that their wings seemed to touch those of their neighbours; and when they flew off at your approach, you would see as many eggs as you had counted birds sitting on the ledge. The eggs vary in size and shape and colour beyond all belief. Some are large, others small, some exceedingly sharp at one end, and others nearly rotund. The rock-climbers assure you that the Guillemot, when undisturbed, never lays more than one egg; but if that be taken away, she will lay another, and so on. They also assure you that when the young Guillemot gets to a certain size, it manages to climb upon the back of the old bird, which conveys it down to the ocean. Having carried a good telescope with me, through it I saw numbers of young Guillemots, diving and sporting on the sea, quite unable to fly; and I observed others on the ledges of the rocks, as I went down among them, in such situations that, had they attempted to fall into the waves beneath, they would have been killed by striking against the projecting points of the intervening sharp and rugged rocks: wherefore I concluded that the information of the rock-climbers was to be depended upon; and I more easily gave credit to it, because I myself have seen an old swan sailing on the water with her young ones upon her back, about a week after they had been hatched.

"He who rejoices when he sees all nature smiling around him, and who takes an interest in contemplating the birds of heaven as they wing their way before him, will feel sad at heart on learning the unmerited persecution to which these harmless sea-fowl are exposed. Parties of sportsmen, from all

quarters of the kingdom, visit Flamborough and its vicinity during the summer months, and spread sad devastation all around them. No profit attends the carnage; the poor unfortunate birds serve merely as marks to aim at, and they are generally left where they fall. Did these heartless gunners reflect, but for one moment, how many innocent birds their shot destroys; how many fall disabled on the wave, there to linger for hours, perhaps for days, in torture and in anguish; did they but consider how many helpless young ones will never see again their parents coming to the rock with food; they would, methinks, adopt some other plan to try their skill, or cheat the lingering hour."

GUINEA-FOWL, or PINTADO. (*Numida meleagris*.) The Guinea-fowls are natives of Africa and its adjacent islands: their manners are similar to those of the domestic poultry, and their food the same. This species is bigger than a large cock; the head is bare of feathers, and covered with a naked bluish skin; on the top is a callous conical protuberance; and on each side of the upper mandible, at the base, hangs a loose wattle, which in the female is red, and in the male bluish: the upper part of the neck is almost naked, being very thinly furnished with a few straggling hairy feathers: the skin is of a bluish ash; the lower part of the neck is

GUINEA-FOWL.—(NUMIDA MELEAGRIS.)

covered with feathers of a purple hue; but the general colour of the plumage is dark bluish gray, sprinkled with round white spots of different sizes, on the whole of the feathers, the breast only excepted, which is of a uniform gray blue: the greater quills are white; and the rest are similar to the upper parts of the plumage, spotted and longitudinally barred with white. Its wings are short, and the tail pendulous, or pointing downwards.

This bird is now common in our poultry yards, but from the circumstance of the young ones being difficult to rear, they are not bred in numbers at all equal to those of the domestic poultry. The female lays many eggs in a season, which she frequently secretes till she has produced her young brood. The egg is smaller than that of the common hen, and of a rounder shape; in colour reddish white, obscurely freckled with a darker colour; and is delicious eating. The Guinea-fowl is a restless and clamorous bird: its voice is harsh and unpleasant, con-

of this fierce animal. [See GLUTTON and WOLVERINE.]

GURNARD. (*Trigla*.) A genus of Acanthopterygious fishes, of which there are several species. The generic characters are—head nearly square, covered with bony plates; two dorsal fins, the rays of the first spinous, those of the second flexible; teeth in both jaws and on the front of the vomer pointed, small, and numerous; seven branchiostegous rays; and three slender appendages at the base of each pectoral fin.

The **GREY GURNARD.** (*Trigla gurnardus*.) This fish is distinguished by its elongated body, and varies from one to two feet in length: the back is of a greenish brown colour, marked with black, yellow, and white spots; the lateral line is very prominent, and strongly serrated; and the sides are of a pale hue, variegated with numerous white spots: the belly is white; the nose long, sloping, and bifurcated. The eyes are large: near the extremity of the gill-covers there is a strong, sharp, long spine; and exactly above the pectoral fins there is another. The first dorsal fin consists of eight spiny rays, and the second of nineteen soft rays; the pectoral fins are transparent, and supported by ten rays, bifurcated from the middle; the ventral fins contain six rays, and the anal nineteen. The Grey Gurnard is common on our coasts, feeding on worms, insects, &c. It bites eagerly at a red bait, and is usually taken with a hook in deep water, though in calm weather they may be seen in considerable numbers on the surface. They make a sort of croaking noise, or *croon*, whence probably arises the name of crooner, by which they are called in Ireland.

The **RED GURNARD**, or **CUCKOO GURNARD.** (*Trigla cuculus*.) This is an elegant species, about a foot in length, and of a slender form; its colour a beautiful bright red, more or less distinctly marked by whitish transverse bars, the sides and belly silvery white. Scales extremely small; lateral line composed of pointed white scales edged with black; a similar row on each side the back: fins transparent; the first dorsal marked on the edge by a black spot; the second tinged near its edge with yellow. It is common on the English coasts; feeds on crustaceous animals; nud spawns in May or June.

The **SAPPHIRINE GURNARD.** (*Trigla hiundo*.) This valuable species is distinguished by the large size of its pectoral fins, which are beautifully edged and spotted with a fine blue colour. It is larger than the preceding, more abundant, and quite equal to many others as food. The head is larger and more flattened than that of the Red Gurnard; the eyes are large; the scales small, oval, and smooth; and the lateral line bifurcates at the tail. It is a native of the European seas; and is frequently taken on the Cornish coasts, and some other parts of this island. By means of its large and long pectoral fins it occasionally springs out of the water to some distance. There are several other species; as the Shining, the Mailed, the Piper, the

Japanese, the Carolina, the Lineated, the Flying, &c.; with the last mentioned of which we shall close our account of the Gurnards.

The **FLYING GURNARD.** (*Trigla volitans*.) This singular and beautiful species is about a foot in length; of a crimson colour above, and pale beneath; the head blunt, and armed on each side with two very strong and large spines pointing backwards. The whole body is covered with strong, sharp-pointed, and closely united scales: the pectoral fins extremely large, transparent, of an olive-green colour, richly marked with numerous bright blue spots: pectoral processes six in number, not separate as in other species, but united, so as to appear like a small fin on each side the thorax: tail pale violet, with the rays crossed by dusky spots, and the base strengthened by two obliquely transverse bony ribs. In the Mediterranean, Atlantic, and Indian seas, the Flying Gurnard swims in shoals; and is often seen darting from the water and sustaining itself for a while in the air, after the manner of the genus *Exocoetus*.

GYMNOPHTHALMIDÆ. The name of a family of Lizards, in which the eyes are distinct and exposed, the eyelids being rudimentary. There are several genera, which will be found described in Mr. Gray's valuable List of the Reptiles in the British Museum; but, important as these are to naturalists, it is quite out of the scope of this work to refer to them.

GYMNOTUS. A genus of Malacopterygious fishes, which contains the well-known *GYMNOTUS ELECTRICUS*, or **ELECTRIC EEL**; a fish possessing the extraordinary property of communicating a sensation similar to an electrical shock, when touched with the hand or an electric conductor. The *Gymnotus* is a fish of a disagreeable appearance, bearing a general resemblance to a large eel, though thicker in proportion, and much darker. It is nearly of equal thickness throughout: the head is broad, depressed, and obtuse: the tail is compressed; and the usual length is from four to five feet, though it is sometimes six, or even eight. It is a native of South America, where it inhabits the larger rivers. The seat of the organs which produce this curious electrical effect is along the under side of

ELECTRIC EEL.—(*GYMNOTUS ELECTRICUS*.)

the tail. They are composed of four bundles of parallel membranaceous laminae, placed very near each other, and nearly horizontally, extended from the skin to the central medial plane of the body, connected together by numerous vertical laminae, arranged transversely. The little cells, or rather the small prismatic and transverse canals, inter-

cepted by these two kinds of laminae, are, according to Cuvier, filled with a gelatinous substance; and the whole apparatus is abundantly supplied with nerves. It is said to possess power, when in full vigour, to knock down a man, and benumb the limb affected, in the most painful manner, for several hours after communicating the shock; and it is by this extraordinary faculty that the *Gymnotus* supports its existence: the smaller fishes and other animals which happen to approach it being stupefied, and thus falling an easy prey to the electrical tyrant. Those who wish to understand the nature of the organs by which this electrical power is produced may find them minutely described by Hunter in vol. 65. of the *Philosophical Transactions*. The following observations are given in Brande's Dictionary: "Although to all outward appearance the *Gymnotus* is nearly allied to the Eel, yet were that part of the body cut off which contains the nutritive, respiratory, and generative organs,—all the parts, in fact, which are essential to the existence of the *Gymnotus* as a mere fish,—it would present a short and thick-bodied form, very different from that of the eel. The long electric organs are tacked on, as it were, behind the true fish, and thus give the *Gymnotus* its anguilliform body. The back bone and muscles are of course co-extended with the electric organs for their support and motion; and the air-bladder is continued along the produced electrophorous trunk, to give it convenient specific levity. Two long dorsal nerves are continued from the fifth and eighth cerebral nerves for ordinary sensation and motion. The spinal chord is continued along the vertebral column, for the exclusive supply of the electrical organs. These organs are four in number; two very large above, and two small ones below. The electricity discharged from them decomposes chemical compounds, produces the spark, and magnetizes iron, as does that of the *Torpedo*. But the magnetizing power seems to be relatively weaker, while the benumbing shock communicated to other animals is stronger than in any other electric fish."

Humboldt has given a lively narrative of the mode of capture of the *Gymnoti*, employed by the Indians of South America. They raise the *Gymnoti* by driving horses and mules into the ponds which those fish inhabit, and harpoon them when they have exhausted their electricity upon the unhappy quadrupeds. "I wished," says Humboldt, "that a clever artist could have depicted the most animated period of the attack: the groups of Indians surrounding the pond, the horses with their manes erect and eyeballs wild with pain and fright, striving to escape from the electric storm which they had roused, and driven back by the shouts and long whips of the excited Indians: the livid yellow eels, like great water-snakes, swimming near the surface and pursuing their prey: all these objects presented a most picturesque and exciting ensemble." In less than five minutes two horses were killed: the eel, being more than five feet in length, glides beneath the body of the horse and

discharges the whole length of its electric organ: it attacks at the same time the heart, the digestive viscera, and, above all, the gastric plexus of nerves. I thought the scene would have a tragic termination, and expected to see most of the quadrupeds killed; but the Indians assured me the fishing would soon be finished, and that only the first attack of the *Gymnoti* was really formidable. In fact, after the conflict had lasted a quarter of an hour, the mules and horses appeared less alarmed; they no longer erected their manes, and their eyes expressed less pain and terror. One no longer saw them struck down in the water; and the eels, instead of swimming to the attack, retreated from their assailants and approached the shore." The Indians now began to use their missiles; and by means of the long cord attached to the harpoon, jerked the fish out of the water without receiving any shock so long as the cord was dry. All the circumstances narrated by the celebrated philosopher, establish the close analogy between the *Gymnotus* and *Torpedo* in the vital phenomena attending the exercise of their extraordinary means of offence. The exercise is voluntary and exhaustive of the nervous energy; like voluntary muscular effort, it needs repose and nourishment to produce a fresh accumulation.

"I was so fortunate (says Professor Owen) as to witness the experiments performed by Professor Faraday on the large *Gymnotus* which was so long preserved alive at the Adelaide Gallery in London. That the most powerful shocks were received when one hand grasped the head and the other hand the tail of the *Gymnotus*, I had painful experience; especially at the wrists, the elbow, and across the back. But our distinguished experimenter showed us that the nearer the hands were together within certain limits, the less powerful was the shock. He demonstrated by the galvanometer that the direction of the electric current was always from the anterior parts of the animal to the posterior parts, and that the person touching the fish with both hands received only the discharge of the parts of the organs included between the points of contact. Needles were converted into magnets: iodine was obtained by polar decomposition of iodide of potassium; and, availing himself of this test, Professor Faraday showed that any given part of the organ is negative to other parts before it, and positive to such as are behind it. Finally, heat was evolved, and the electric spark obtained."

There are several other fish belonging to the *Gymnotus* tribe; but they are much smaller; and whether they possess any electric power is a matter of great doubt: yet the structure of the lower part of their bodies seems to imply a similar contrivance of nature. Most of them are natives of the same climate as the *Gymnotus Electricus*, and are considered edible food. The principal are the *Carapo Gymnote*, the *Rostrated Gymnote*, and the *White Gymnote*.

GYMNURA. An insectivorous animal belonging to the family *Erinaceada*, inha-

biting Sumatra. In its dentition and spiny covering it closely resembles the Hedgehog tribe; but it has the long, naked, scaly tail and pointed muzzle of the Shrews. Its generic character has been given by Dr. Horsfield and Mr. Vigors: Head elongated, acuminate, compressed on the sides, flattish above; muzzle obtuse, elongated, and projecting forward considerably beyond the lower jaw; tongue rather smooth, large; auricles rounded, somewhat prominent, naked; eyes small; nostrils lateral, prominent, with the margins convoluted; vibrissae elongated. Body rather robust; the short fur soft, but with distant, erect, subelongated hairs; tail rather long, smooth, naked, and scaly. Feet plantigrade, pentadactyle, the fore-feet with a rather short thumb. Claws narrow, curved, very acute, and retractile. The body, legs, and first half of the tail are black; the head, the neck, and the shoulders are white; and a black band passes over the eyes. Cuvier, in his "Règne Animal" (1829), observes that the genus *Gymnura* of MM. Vigors and Horsfield appears to approach Cladobates in its teeth, and the Shrews in its pointed muzzle and scaly tail. It has five unguiculated toes on all its feet, and rather stiff bristles projecting forth from the woolly hair. The species is called *G. RAFFLESII*, in compliment to the accomplished founder of Singapore, Sir Stamford Raffles.

GYPAETUS, or BEARDED VULTURE.

A genus of birds which may be considered as intermediate between the eagles and vultures. The BEARDED VULTURE (*Gypætus barbatus*), sometimes called the Bearded Griffin or *Lammergeyer*, is the largest bird of prey belonging to the Eastern Continent, and it appears to be the only Vulture which has ever been found in a wild state in Britain. It usually inhabits the high chains of mountains, and nestles in inaccessible accli-

BEARDED VULTURE — (*GYPAETUS BARBATUS*.)

vities. It is found in Europe as far north as Astracan, but is much more common in Spain, on the Pyrenees, Portugal, the isle of Elba, Tuscany, Malta, Turkey, and in the Archipelago; but is nowhere so abundant as in South Africa, in which quarter it attains a larger size than elsewhere. In the adult bird the head and upper part of the neck are of a dirty white colour; a black stripe extends from the base of the beak,

and passes above the eyes; another, arising behind the eyes, passes over the ears; lower part of the neck, breast, and belly, orange-red; mantle, back, and wing-coverts, deep grey-brown, but on the centre of each feather is a white longitudinal stripe: wings and tail-feathers ashy-grey, the shafts white; tail long, very much graduated; beak and claws black; feet blue; iris orange, eye surrounded by a red lid. Length about four feet and a half.

"Unlike the typical vultures," says Mr. Gould, "which are distinguished by their bare necks, indicative of their propensity for feeding in a carriou, the Lammergeyer has the neck thickly covered with feathers, resembling those of the true eagles, with which it also accords in its bold and predatory habits, pouncing with violent impetuosity on animals exceeding itself in size: hence the young chamois, the wild goat, the mountain hare, and various species of birds find in it a formidable and ferocious enemy. Having seized its prey, the Lammergeyer devours it upon the spot, the straight form of their talons disabling them from carrying it to a distance. It refuses flesh in a state of putrefaction, unless sharply pressed by hunger; hence nature has limited this species as to numbers: while, on the other hand, to the Vultures, who are destined to clear the earth from animal matter in a state of decomposition, and thus render the utmost service to man in the countries where they abound, she has given an almost illimitable increase."

GYRINUS: GYRINIDÆ. A genus and family of aquatic Beetles, the type of which is known under the name of Whirligigs, or Water-flea, from its peculiar motions. They are in general of small or moderate size and are to be seen, from the first fine days of spring till the end of autumn, on the surface of quiet waters, and even upon that of the sea, often appearing in great numbers, and appearing like brilliant points. They are active swimmers, and curvet about in every direction. Sometimes they remain stationary without the slightest motion; but no sooner are they approached, than they escape by darting under the surface of the water, and swimming off with the greatest agility. The four hind-legs are used as oars, and the anterior ones for seizing the prey: when they dart beneath the surface, a bubble of air like a silvery ball remains attached to the hind part of the body. When seized, they discharge a milky fluid, which spreads over the body, and probably produces the disagreeable odour which they then emit. There are several species found in this country, but it is not necessary to describe them separately. These beetles are almost the only water insects which exhibit a brilliant metallic lustre, a peculiarity dependent upon the habits of the insects which generally swim upon the surface of the water.

HADDOCK. (*Gadus aeglefinus*.) This well-known Malacopterygious fish is nearly allied to the cod; and, like it, is a native of the Northern seas, where it assembles in prodigious shoals, visiting particular

constants at stated seasons. Nor is it by any means scarce on the shores of Britain or Ireland; immense quantities, indeed, are taken at different localities, particularly along our eastern coast; and as its flesh is sweet and wholesome, and can be preserved with facility, it is a fish of considerable value. The Haddock is generally about twelve or fourteen inches in length, and weighs from two to three pounds; though, occasionally, they are met with

HADDOCK — (*GADUS ELEFINUS*.)

nearly three feet long, and weighing ten or twelve pounds: the smaller or moderate sized ones, however, are most esteemed for the table. The body is long and slender; the head slopes suddenly down from the crown to the point of the nose; the lower jaw is longer than the upper, and furnished with a narrow band of teeth: the barbule at the chin is small; the eye is large, and the irides silvery; the head, cheeks, back, and upper part of the sides, are of a dull grayish hue; lower part of the sides and belly, silvery. On each side, is a large black spot, (of which we shall again have to speak.) The lateral line is black: the dorsal fins and tall dusky bluish gray; pectoral, ventral, and anal fins lighter: the tail bifid. Their food is: small fish, crustacea, and marine insects: they spawn in February and March; and they are in the best condition for the table from October to January. In stormy weather this fish is said to imbue itself in the ooze at the bottom of the sea; and those which are taken shortly after are observed to have mud on their backs.

We are always loth to make allusion to ignorant superstitions, however popular they may be, unless we can furnish some rational solution for their existence; but they have sometimes taken such deep root, that not to mention, might almost seem to sanction them. We of course allude to the "thumb and finger marks of St. Peter;" and shall therefore extract from Mr. Yarrell's excellent work the following remarks, as supplying additional information of a germane character: "Pennant says, 'Our countryman Turner suggested that the Haddock was the *Opos* or *Asinus* of the ancients. Different reasons have been assigned for giving this name to the species, some imagining it to be from the colour of the fish, others because it used to be carried on the backs of asses to market.' A different reason appears to me more likely to have suggested the name: the dark mark on the shoulder of the Haddock very frequently extends over the back and unites with the patch of the shoulder on the other side, forcibly reminding the observer of the dark stripe over the withers of the ass; and the superstition that assigns the mark in the Haddock to the

impression St. Peter left with his finger and thumb when he took the tribute-money out of a fish of this species, which has been continued to the whole race of Haddocks ever since the miracle, may possibly have had reference, or even its origin, in the obvious similarity of this mark on the same part of the body of the Haddock and of the humble animal which had borne the Christian Saviour. That the reference to St. Peter is gratuitous, is shown by the fact that the Haddock does not exist in the sea of the country where the miracle was performed." Independently of which, the Sea of Galilee is a large fresh water lake.

HÆMATOPUS, or OYSTER-CATCHER. A genus of wading birds, the best known species of which is the Common Oyster-Catcher, *H. ostralegus*. [See OYSTER-CATCHER.]

HAG. [See *GASTRONOMUS*.]

HAIR-STREAK (BUTTERFLY). A name given to various species of Butterflies, of the genus *Thecla*.

HAKE. (*Gadus merluccius* of Linnaeus.) This Macropterygious fish inhabits the seas of the north of Europe and the Mediterranean; it is also found on the western and southern coasts of England, as well as on various parts of the coast of Ireland. It is of a lengthened form, generally from one to two feet, but sometimes more: the head is rather large, broad and flat at the top, but compressed on the sides; wide mouth; lower jaw the longest; teeth slender and sharp, with a single row in each jaw: the colour of the body is a dusky brown above, and lighter beneath; dorsal and caudal fins dark; ventral and anal fins light brown; the pectoral and ventral fins are of moderate size, and of a sharpened shape; and the tail is nearly even at the end. It is salted and dried in the manner of cod, haddock, &c., but is not considered as a delicate fish either in its fresh or salted state, and is rarely admitted to the tables of the affluent: it forms, however, a very useful article of food for the lower orders in many parts both of our own and other countries. It is a very voracious fish; and when pilchards approach the shores, it follows them, continuing in great numbers through the winter; so that when pilchards are taken in a sea, on the Cornish coast, many Hakes are generally found inclosed with them. By Dr. Fleming and other naturalists, this fish is regarded as belonging to a distinct genus, characterized by having one anal and two dorsal fins. (*Merluccius*.)

HALCYON. A genus of the Kingfisher family, of which there are many species:— of these we may specify the **SACRED KINGFISHER** (*Halcyon sanctus*), which is generally distributed over the Australian continent, and feeds on various insects and reptiles; as Mantidæ, grasshoppers, caterpillars, lizards, and small snakes; and Mr. Gould found that specimens killed in the vicinity of salt marshes had their stomachs literally crammed with crabs and other crustaceans.

animals. It also excavates holes in the nests of a species of ant which are constructed around the holes and dead branches of the *Eucalypti*, feeding on the larva, a most favourite food.

HALIBUT, or HOLIBUT. (*Hippoglossus*. This is the largest fish belonging to the *Pleuronectidae* or Flat-fish family, attaining the length of six or seven feet in the northern seas, and weighing from 300 to 400 lbs. In shape and fins the Halibut is like the Flounder; and the lateral line is arched. Its flesh is rather coarse and dry, but it ad-

HALIBUT. — (*HIPPOGLOSSUS VULGARIS*)

mits of being salted. In some of the smaller species, which are found in the Mediterranean, the eyes look towards the left side, instead of towards the right, the latter being the ordinary rule of the family; and when that happens it is said to be "reversed."

HALICHERUS. A genus of Seals. [See SEAL.]

HALICHONDRIA. A genus of Sponges, in which the cartilaginous skeleton is strengthened by siliceous spicules. See Dr. Fleming's British Animals, and Dr. Johnston's British Sponges, for an account of the many entirely British species.

HALICORE. A genus of Cetaceous animals, found in the Eastern seas. [See DUGONG.]

HALIOTIS: HALIOTIDÆ. A genus and family of Gasteropodous Mollusca, not widely different from the Limpets, and having the Haliotis or Ear-shell as the type. These splendid shells are remarkable for the pearly iridescence of the inner surface, and the row of holes following the course of the spine. [See EAR-SHELL.]

HALMATURUS. A genus of Marsupialia belonging to the Kangaroo family. As an example we may give Parry's Kangaroo, *Halmaturus Parryi*, a species familiar to the colonists and natives of New South Wales. It is very shy, escapes with great fleetness from its pursuers, and inhabits the mountainous parts. It is easily tamed, becoming very familiar. The male measures five feet from the nose to the end of the tail. The body is bluish gray, whitish beneath; the head brownish; a white streak on the face below the eye, and a short one on each eyebrow. Capt. Sir Edward Parry has given an interesting account of its habits in confinement. Those who wish to get further information on this genus and its allies must consult the noble monograph of the Kangaroos, by John Gould, F. R. S., where all the species

are admirably figured and described. The reader may consult also with profit, Mr. Waterhouse's History of Mammalia, and the volume on Marsupialia in the Naturalist's Library.

HALTICIDÆ. The scientific name *Haltica*, derived from a word signifying to leap, has been applied to a family of insects allied to the Chrysomelidæ, and popularly known as flea-beetles. The following are their chief peculiarities:—The body is oval and very convex above; the thorax is short, wide behind and narrow before; the head is pretty broad; the antennæ are slender, about half the length of the body, and are implanted nearly on the middle of the forehead; and the hindmost thighs are very thick, being formed for leaping. The surface of the body is smooth, generally polished, and often prettily or brilliantly coloured. The claws are very thick at one end, are deeply notched towards the other, and terminate with a long, curved, and sharp point, which enables the insect to lay hold firmly upon the leaves of the plants on which they live. These beetles eat the leaves of vegetables, preferring especially plants of the cabbage, turnip, mustard, cress, radish, and horse-radish kind, or those which, in botanical language, are called cruciferous plants, to which they are often exceedingly injurious. The flea-beetles conceal themselves, during the winter, in dry places, under stones, in tufts of withered grass, and in chinks of walls. They lay their eggs in the spring, upon the leaves of the plants upon which they feed. The larvæ of the smaller kinds burrow into the leaves, and eat the soft pulpy substance under the skin, forming therein little winding passages, in which they finally complete their transformations. Hence the plants suffer as much from the depredations of the larvæ as from those of the beetles, a fact that has too often been overlooked. The larvæ of the larger kinds live exposed on the surface of the leaves which they devour, till they come to their growth, and go into the ground, where they are changed to pupæ, and soon afterwards to beetles. The mining larvæ are little slender grubs, which arrive at maturity, turn to pupæ, and then to beetles in a few weeks. Hence there is a constant succession of these insects, in their various states, throughout the summer. One of the most destructive species of this family is the Turnip-flea (*Haltica nemorum*), [which see].

HAMSTER. (*Cricetus frumentarius*.) A rodent animal, of the rat tribe, distinguished by two enormous cheek pouches, which will hold a quarter of a pint, and by its remarkable instincts. It inhabits the sandy districts of the north of Europe and Asia, Austria, Silesia, and many parts of Germany, Poland, &c., and is very injurious to the agriculturist, on account of the quantity of grain it devours. The general size of the Hamster is nearly that of a brown or Norway rat, but it is of a much thicker form, and has a short and somewhat hairy tail. Its colour is a pale reddish brown above, and black beneath: the muzzle is whitish, the cheeks

reddish, and on each side the body are three white spots, those on the shoulders being the largest: the ears are rather large, and rounded. On the hind feet are five toes, and on the fore feet are four, with a claw in place of a fifth. They sometimes vary in colour; and the male is invariably larger than the female. The quantity of grain which they consume is very great; and what they cannot devour, they carry off in their cheek-pouches, and deposit in their holes for their winter subsistence. Their dwellings are formed under the earth, and consist of more or fewer apartments, according to the age of the animal: a young Hamster makes them hardly a foot deep; an old one sinks them to the depth of four or five feet, and the whole diameter of the residence, taking in all its habitations, is sometimes eight or ten feet. The principal chamber is lined with dried grass, and serves for a lodging: the others are vaults destined for the preservation of provisions, of which he amasses a great quantity during the autumn. Each hole has two apertures; the one descending obliquely, and the other perpendicularly, and it is through the latter that the animal makes its ingress and egress. The holes of the females, who never reside with the males, have more numerous passages. The female breeds two or three times a year, producing from six to ten, and sometimes more: the growth of the young is very rapid, and at about the age of three weeks the old one forces them out of the burrows to shift for themselves.

The Hamster is carnivorous as well as granivorous, for though it feeds on all kinds of herbs as well as corn, it occasionally attacks and devours the smaller kinds of animals. On the approach of winter the Hamster retires into his subterranean abode, the entry of which he closes with great care; and thus remaining tranquil and secure, feeds on his collected store till the frost becomes severe: he then falls into a profound slumber, and in that dormant state continues rolled up, apparently lifeless, his limbs inflexible and his body perfectly cold. This lethargy of the Hamster has been generally ascribed to the effect of cold alone: but more recent observations have proved, that unless at a certain depth beneath the surface, so as to be beyond the access of the external air, the animal does not fall into its torpid state, and that the severest cold on the surface does not affect it. On the contrary, when dug out of its burrow and exposed to the air, it infallibly wakes in a few hours. The waking of the Hamster is a gradual operation: he first loses the rigidity of his limbs, then makes deep inspirations, at long intervals; after this he begins to move his limbs, open his mouth, and utters an unpleasant rattling sound: he at length opens his eyes, and endeavours to rise, but reels about for some time, as if in a state of intoxication, till at length he perfectly recovers his usual powers. When exposed to a cold air he is sometimes two hours in waking; but in a warmer air the transition is effected in half the time. The character which naturalists have given of these animals is very unfavourable. They

constantly reject all society with one another, and they will not only destroy every animal which they are capable of conquering but will fight, kill, and devour their own species: yet, fierce as they are, they quail before their deadly enemy the polecat, which chases them into their holes, and unrelentingly destroys them. The fur of the Hamster is said to be valuable; and the peasant who 'goes a hamster nesting' in the winter, obtains not only the skin of the animal, but his hoard, which is said commonly to amount to two bushels of good grain in each magazine. Buffon says, that in Gotha, where these animals were proscribed on account of their vast devastations among the corn, 146,132 of their skins were delivered at the Hotel de Ville of the capital in the course of three years.

HARE. (*Lepus*.) A well-known genus of Rodent mammalia, containing several species. We shall first describe —

The **COMMON HARE** (*Lepus timidus*), which possesses all the characters of the genus *Lepus* in such a degree as to form its most perfect type. Its hearing and sight are most acute; its timidity is unequalled; and its swiftness is surpassed by none. The general length of the Hare is about two feet; the colour a sub-ferruginous gray, with the chin and belly white: the throat and breast ferruginous, and

COMMON HARE.—(*LEPUS TIMIDUS*.)

the tips of the ears blackish: the tail is blackish above, and white below: the feet are covered beneath as well as above with fur; the upper lip is divided; the eyes are large, prominent, and placed laterally; and they are said to be constantly open even during sleep: the hinder legs are much longer than the fore legs; the feet are hairy; and the tail is short and turned up. Its favourite residence is in rich and somewhat dry and flat grounds, and it is rarely discovered in very hilly or mountainous situations. It feeds principally by night, and remains concealed during the day in its form, beneath some bush or slight shelter. To this spot it constantly returns, and becomes so attached to it, that it is with difficulty compelled to abandon it: in choosing its place of rest, however, it is governed by the seasons, and while a cool and shady spot is its resort in summer, it selects for its winter lair a situation where it can best receive the genial warmth of the sun.

The Hare is a very prolific animal, generally producing three or four young at a time, and breeding several times in a year. The eyes of the young are open at birth: the dam suckles them about twenty days, after which they leave her, and procure their

own subsistence. Its food consists of various kinds of herbage, but it prefers vegetables of a milky and succulent quality, and is especially fond of parsley. It is at times a very annoying and destructive invader, not only of the field and garden, doing great injury to the young wheat and other grain; but it also frequently commits sad havoc in young plantations, by gnawing off the bark, and feeding on the young shoots of various shrubs. It is proverbially timid, and flies if disturbed when feeding, at the slightest alarm; and, led by a natural instinct, it invariably makes towards the rising ground, the length of its hind legs giving it an advantage in this respect over its pursuers. These animals seldom migrate far from the spot where they are produced; but each makes a farm at a small distance, showing a predilection rather for the place of their nativity than the society of their kind. They pair in February; and as they only quit their couch in the night time to obtain food, so they never leave it for the companionship of their mates but at the same silent hour: often, indeed, are they observed by moonlight, playing and skipping about in the most sportive manner; but the slightest breeze, or even the falling of a leaf, is sufficient to disturb their revels; and they instantly fly off, each pursuing a different track.

In order to enable this creature to perceive the most distant approaches of danger, nature has provided it with very long ears, which, like tubes applied to the auditory organs of deaf persons, convey to it such sounds as are remote; and the motions of the Hare are directed accordingly. Its large prominent eyes being placed so far backward as to receive the rays of light on every side, it can almost see distinctly behind while it runs directly forward. The muscles of its body being strong, and unencumbered with fat, it has no superfluous burden of flesh to carry; and to assist it in escaping from its pursuers, the hinder legs are considerably longer than the fore, which adds to the swiftness of its motions. But they generally exhaust their powers by their first efforts, and are consequently much more easily caught than foxes, though these wily creatures are slow when compared with them. When the Hare hears the hounds at a distance, it flies for some time from a natural impulse, till having gained some hill or rising ground, and left the dogs so far behind that their cries no longer reach its ears, it stops, rears on its hinder legs, and looks back, for the purpose of satisfying itself whether its enemies are still in sight or not: but the dogs having once gained the scent, trace it with united and unerring skill; and the poor animal soon again receives indications of their approach. Sometimes, when hard hunted, it will start a fresh Hare, and squat in the same form; at others, it will creep under the door of a sheep-cot, and conceal itself among the sheep; sometimes it will enter a hole, like the rabbit; at others, it will run up one side of a quickset hedge, and down the other; and it has been known to ascend the top of a cut hedge, and run a considerable way, by which stratagem it

has effectually evaded the hounds. It is also not unusual for the Hare to betake itself to furze bushes, and leap from one to another, whereby the dogs are frequently misled; and as it swims well, and takes the water readily, it will cross a river with the same intent, if it has the opportunity. It may be observed, however, that the first donbling which a Hare makes generally affords a key to all its future attempts of that kind, the latter exactly resembling the former. The Hare is a short-lived animal, and is supposed rarely to exceed the term of seven or eight years. Its voice, which is seldom heard but in the distress of sudden surprise or when wounded, resembles the sharp cry of an infant. Its enemies are numerous and powerful. Every species of the dog kind pursues it by instinct; the cat and the weasel tribes exercise all their arts to ensnare it; and birds of prey, snakes, adders, &c. drive it from its form, particularly during the summer season: these, with the more destructive pursuits of mankind, contribute to this the number of these animals, which from their prolific nature would otherwise multiply to an extravagant degree.

The flesh is now much prized for its peculiar flavour, as it was by the Romans; but it was forbidden to be eaten among the Jews, Mahometans, and ancient Britons. The fur, until of late years, when silk became so generally used, was of great importance in the manufacture of hats; and in some parts of the continent it is also woven into cloth.

THE IRISH HARE (*Lepus Hibernicus*), usually considered a species of the common Hare of England, is said by Mr. Bell, in his "British Quadrupeds," to be specifically distinct. In support of his opinion, he says, "The characters in which it principally differs from the latter are as follows:—It is somewhat larger; the head is rather shorter; the ears are even shorter than the head, while those of the English Hare are fully an inch longer; the limbs are proportionally rather shorter; and the hinder legs do not so much exceed the fore legs in length. The character of the fur is also remarkably different: it is composed exclusively of the uniform soft and shorter hair which in the English species is mixed with the black-tipped long hairs, which give the peculiar mottled appearance of that animal; it is therefore of a uniform reddish brown colour on the back and sides. The ears are reddish gray, blackish at the tip, with a dark line near the outer margin. The tail is nearly of the same relative length as in the common species. The numerous discrepancies in the colour and texture of the fur, and in the form and proportion of the different parts of the animal, appear to me to be too important to constitute merely the characters of a variety."

THE SCOTCH, OR VARYING HARE. (*Lepus variabilis*.) This species, which is intermediate in size between the Common Hare and the Rabbit, differs greatly in its habits from both. Though confined to alpine dis-

tricts (and therefore sometimes called the Alpine Hare), it is diffused through a wide geographical range; being found on the Alps, in Norway, Sweden, Lapland, Russia, Siberia, and Kamtschatka, and occurring also in our own island on the summits of the Scottish mountains. In summer its colour is a tawny gray, with a slight admixture of black; in winter it is entirely white, except the tips of the ears, which are black. It shelters itself in the cliffs of rocks, is easily tamed, and becomes extremely playful and amusing. Towards the month of September it changes its colour, and resumes its summer dress about April; but in the intensely cold climate of Siberia it continues white all the year round. It has been sometimes found entirely coal black; a variety which is also known to take place occasionally in the common species. When the winter has proved unusually severe, the Varying Hare has been known to migrate from the frozen hills of Siberia, and to descend, in troops of five or six hundred, into the plains and woody districts, where they remained till the returning spring.

In the southern and western provinces of Russia there is a mixed breed of Hares, which sustains only a partial loss of its colour; the sides, and the more exposed parts of the ears and legs, becoming white in the coldest months, while the other parts remain unchanged. This variety is by the Russians called Russak; and prodigious numbers are taken in snares for the sake of their skins only; the Russians and Tartars, like our own druidical ancestors, holding the flesh of Hares in the utmost detestation.

The AMERICAN HARE (*Lepus Americanus*) is not much larger than a rabbit, by which name indeed it is well known throughout the northern parts of that vast continent. The summer hair is dark brown on the upper part of the head, lighter on the sides, and of an ash colour below; the ears are wide, edged with white, tipped with brown, and dark coloured behind; tail dark above, white beneath, having the under surface turned up; the fore legs are shorter and the hinder longer in proportion than those of the European. In the middle and southern states, the change in the colour of the hair is by no means as remarkable as it is farther north, where it becomes nearly white. It is not hunted in America, but is generally roused by a dog, and shot or caught by means of snares or a common box-trap, the latter being the most usual mode. It has the same kind of leaping gait as the European hare; and, like that animal, it breeds several times during the year. It is not of a migratory nature, but always continues to haunt the same places, taking occasional refuge under the roots of trees, or in the hollows near the roots.

In Mr. Gosse's "Canadian Naturalist" we find the following information respecting the American Hare:—"It is found pretty generally over North America, from this province, even to the Gulf of Mexico, where it is more common than it is with us. Here its winter coat is nearly white, but in summer

it is of a yellowish brown, with a white tail. It makes a nest or bed of moss and leaves in some hollow tree or old log, whence it issues chiefly by night. Though not so much addicted to gnawing as the squirrels, yet as its teeth are formed in the same manner, it probably resembles them in its food, eating various kinds of nuts and seeds, as well as green herbs. It is said also occasionally to peel off the bark from apple and other trees. A singular mode of taking furred animals out of hollow trees, logs, &c. is practised in the south, called 'twisting.' I once saw it performed on a rabbit (so called); the dogs had tracked him and driven him to his hole in the bottom of a hollow hickory tree. The hole was too small to admit the hunter's hand with convenience, so we made the negroes cut down the tree, which was soon effected. When it fell, we watched the butt, to see that the rabbit did not run out, but he did not make his appearance. The hunter then got some long slender switches, and probing the hollow, found that the rabbit was at the farther end several feet up the trunk. He now commenced turning the switch round in one direction, a great many times, until the tip of it had become so entangled in the animal's fur, as to bear a strong pull. He then began to pull steadily out, but the rabbit held on as well as he could, and made considerable resistance, crying most piteously, like a child; at last the skin gave way, and a great mass of fur and skin came out attached to the switch, pulled off by main force. He now took a new switch, and commenced twisting again, and this time pulled the little thing down, but the skin was torn almost completely off the loins and thighs of the poor little creature, and so tightly twisted about the end of the stick, that we were obliged to cut the skin to get the animal free!" A more cold-blooded or barbarous cruelty, practised on a harmless and defenceless animal, it is scarcely possible to conceive; and were it not for the undoubted veracity of the writer we should reject it as well on the score of its incredibility as of its inhumanity.

The CAPE HARE. (*Lepus Capensis*.) This species, which is about the size of the one last described, inhabits the country near the Cape of Good Hope, frequenting the most rocky and mountainous situations, and taking up its abode in the fissures of the cliffs. The ears are long, broad in the middle, naked, and rose-coloured on the outside, and covered with short grey hairs within: the back and upper parts generally are similar in colour to that of the Common Hare; the cheeks and sides are cinereous; the breast, belly, and legs, ferruginous; and the tail, which is bushy, turns upwards. At the Cape it is called the Mountain Hare, or VLAKTE HAAS. In one of the specimens in the British Museum the nape of the neck has two white streaks.

The BAIRAL HARE (*Lepus Tula*) is rather larger than the common Hare, and has a longer and smaller head, but in colour and general appearance, pretty much resembles it. This animal is an inhabitant of the open

hilly places in Dauria and Mongolia, and is said to extend as far as Tibet. In the colour of its flesh it agrees with the rabbit, but differs both from that animal and the hare in its manners; neither burrowing in the ground, like the former, nor running far when pursued, like the latter; but instantly taking refuge in the holes of rocks. [For Alpine Lagomys, Calling Hare, &c., see LAGOMYS.]

HARELDA. A genus of Ducks, containing the Long-tailed Duck (*H. glacialis*). [See DUCK.]

HARENGUS. [See HERRING.]

HARFANG. The Great Snowy Owl. [See OWL.]

HARLEQUIN BEETLE. [See ACRO-CINUS.]

HARLEQUIN DUCK. (*Clangula histrionica*). A magnificent species found on

HARLEQUIN DUCK.
(CLANGULA HISTRIONICA.)

both continents; it derives its name from the singularity of its markings. It is seventeen inches in length, and twenty-eight inches in extent: the bill is of a lead colour, tipped with red; upper part of the head black; between the eye and bill a broad space of white, extending over the eye, and ending in reddish; behind the ear, a similar spot; neck black, ending below in a circle of white; breast deep slate; shoulders marked with a semicircle of white; belly black; sides chestnut; body above, black, or deep slate; some of the scapulars white; greater wing-coverts tipped with white; legs and feet deep ash; vent and pointed tail black. It swims and dives well; flies swift, and to a great height; and has a whistling note. The female lays ten white eggs on the grass; the young are prettily speckled. At Hudson's Bay, where it breeds, and is said to frequent the small rivulets inland, it is called the Painted Duck; at Newfoundland and along the coast of New England, the Lord. It is an admirable diver, and is often seen in deep water, considerably out at sea.

HARPA, or HARP-SHELL. A beautiful genus of shells, so regularly marked

with parallel longitudinal ribs on the outer surface, as to suggest at the first glance the idea of the stringed instrument to which it owes its name. The upper end of each rib is projected and pointed; spire short, last whorl large and deeply notched; outer lip thickened, and is supposed to have no operculum. The Mollusc which inhabits it has the head large; mouth open below; destitute of a proboscis; but having two ten-

HARP SHELL AND ANIMAL.
(HARPA VENTRICOSA.)

tacula, with eyes in the middle: foot large. It has been asserted by some naturalists that the animal can, when attacked by an enemy, disembarass itself of part of its foot, and retire entirely within its shell. The principal localities of this genus are the Red Sea and the Indian and South American Oceans. There are several species, all handsome, and some rare; among them the *Harpa multicastrata*, which is very rare, and the *Harpa imperialis*, from the Mauritius, the markings of which are very elegant; but perhaps the more abundant species here figured, *Harpa ventricosa*, is as beautiful in form and colouring as any species of this marine carnivorous genus.

HARP-SEAL. The Greenland Seal. [See SEAL.]

HARPY EAGLE. (*Thrasaetus*). A genus of Accipitrine Birds found in South America; celebrated for the enormous development of their beak and legs, and the consequent strength and power they evince in mastering their prey. The following short but characteristic notice of this bird occurs

HARPY EAGLE — (THRASAETUS HARPYIA.)

in "Edwards's Voyage up the Amazon." "While absent upon this excursion, Mr. Bradley, an Irishman, who trades upon the Upper Amazon, arrived at Mr. Norris's,

bringing many singular birds and curiosities of various kinds. One of the former was a young Harpy Eagle, a most ferocious looking character, with a harpy's crest and a beak and talons in correspondence. He was turned loose into the garden, and before long gave us a sample of his powers. With erected crest and flashing eyes, uttering a frightful shriek, he pounced upon a young ibis, and quicker than thought had torn his reeking liver from his body. The whole animal world there was wild with fear." No member of the Bird class could look more fierce and indignant than a noble specimen of this formidable Eagle, which we saw some years ago in the Zoological Gardens, Regent's Park. Its whole aspect was that of formidably organized power; and even the appendage of the crest added much to its terrific appearance.

HARRIER. A well-known kind of hound, remarkable for his sagacity in tracing, and boldness in pursuing his game. There are several varieties, but all differing in their services; some being adapted for one sort of game, and some for another. The best breed, and that to which the name is more

HARRIER.

emphatically applied, is the Harrier used for hunting the Hare, which is supposed to have been originally produced by a cross between the Foxhound and the Beagle. The Harrier is generally from sixteen to eighteen inches in height.

HART. The name given to a Stag or male Deer, which has completed his fifth year. [See DEER.]

HARVEST-FLY. [See CICADA septemdecim.]

HAWFINCH. [See GROUSE.]

HAWK. (*Falconidae*.) The name by which several birds of prey, closely allied to the Falcons, are designated; as the Goshawk, the Sparrow-hawk, &c., which will be found under their respective names. The beak of the Hawks resembles that of the Falcons in its general form, being curved from the base; but the wings are shorter, and want the pointed tips which are characteristic of that division of the family. The most powerful Hawks are found in cold countries, inhabiting hilly districts where there are woods, and seeking their prey near the ground. Among the whole, none is more bold and pertinacious in pursuit of its prey than the Sparrow-hawk [which see]. In the first volume of Gray and Mitchell's genera

of Birds will be found descriptions of the numerous genera, with references to the greater part of the species, and figures of most of the typical forms. In the List of Birds in the British Museum collection, which is exceedingly rich in the Hawk tribe, will be seen how numerous the species are. We refer those desirous of further information to those two works.

HAWK-OWL. [See OWLS.]

HAZEL WORM. [See SLOW-WORM.]

HEATHCOCK. [See GROUSE.]

HECTOCOTYLUS. [See SUPPLEMENT.]

HEDGEHOG. (*Erinaceus Europæus*.) The common Hedgehog is found in most of the temperate parts of Europe and Asia; and though it has a formidable appearance, it is one of the most harmless creatures in existence. It is an insectivorous quadruped, whose generic character may be thus described:—the back covered with sharp strong spines, about an inch long, with the power of rolling itself up in a ball by means of appropriate muscles; muzzle pointed; tail short; and each foot five-toed and armed with robust claws; the head is very conical; the ears short, broad, and rounded; the eyes prominent; the body oblong, and conical above; and the legs short, almost naked, and of a dusky colour. It is about ten inches in length, and its colour is generally a grey-brown. Its close covering of sharp spines, which are firmly fixed in its tough skin, and sufficiently elastic to bear great violence without breaking, protects it from falls or blows, and as effectually secures it from the attacks of an enemy; for when molested, it instantly rolls itself into a kind of ball, and presents nothing but its prickles to the foe; and the more the animal is irritated and alarmed, the more firmly does it contract itself, and the more stiff and strong does its bristly panoply become. Thus rolled up, it patiently waits till the danger is past; the cat, the weasel, the ferret, and the martin soon decline the combat; and though a well-trained wire-haired terrier, or a fox, may now and then be found to open a Hedgehog, it generally remains impenetrable and secure. From this state of security, in fact, it is not easily forced; scarcely anything but cold water obliging it to unfold itself.

The usual food of the Hedgehog is beetles, worms, slugs, and snails; it is also said to devour fruit, the roots of plants, and certain other vegetable substances, while it shows itself not so restricted as has been thought in its choice of animal food; eggs, frogs, toads, mice, and even snakes occasionally, serving for its repast. The Hedgehog is strictly nocturnal, remaining coiled up in its retreat during the day, and wandering about nearly all the night in search of food. It generally resides in small thickets, in hedges, or in ditches covered with bushes, making a hole about six or eight inches deep, which it lines with moss, grass, or leaves. The hibernation of the Hedgehog is undoubted;

although it lays up no store for the winter, it retires to its hole, and in its warm, soft nest of moss and leaves, it lies secure from the rigours of the frost and the violence of the tempest, passing the dreary season in a profoundly torpid state. The female produces from two to four young ones early in the summer, which at their birth are blind, and covered with soft white spines, which in two or three days become hard and elastic. The flesh of these animals, though generally rejected as human food, is said to be very delicate.

Many absurd errors prevail as to the habits of this animal. It is charged with sucking the teats of cows by night, and wounding their udders with its spines, thereby causing those ulcerations which are sometimes observed: from this false accusation, however, the smallness of its mouth is a sufficient exculpation. It is also said to be very destructive to gardens and orchards, by rolling itself among fruit, and thus carrying off a quantity on its spines: but its spines are evidently so disposed, that no fruit would stick on them, even were the experiment attempted. But so far from being mischievous and injurious, the Hedgehog is found to be of real use, and is often kept for the purpose of ridding houses of the numerous cockroaches by which some are infested; and it is well known to devour many destructive insects of the beetle kind and others, which are injurious to the farmer and gardener.

In the *Journal of a Naturalist*, this animal is thus noticed:—"Notwithstanding all the persecutions from prejudice and wantonness to which the Hedgehog is exposed, it is yet common with us; sleeping by day in a bed of leaves and moss, under the cover of a very thick bramble or furze-bush, and at times in some hollow stump of a tree. It creeps out in the summer evenings; and, running about with more agility than its dull appearance promises, feeds on dew-worms and beetles, which it finds among the herbage, but retires with trepidation at the approach of man. In the autumn, crabs, fruits, haws, and the common fruits of the hedge, constitute its diet. In the winter, covering itself deeply in moss and leaves, it sleeps during the severe weather; and, when drawn out from its bed, scarcely anything of the creature is to be observed, it exhibiting only a ball of leaves, which it seems to attach to its spines by repeatedly rolling itself round in its nest."

The **SIRRIAN or LONG-EARED HEDGEHOG**. (*Eriacus auritus*.) This species is in general larger than the common or European, and may be easily distinguished by its ears, which are large, oval, open, and naked, with soft whitish hair on the inside, and edged with brown: the upper part of the animal is covered with slender brown spines, with a whitish ring near the base, and another towards the tip, and the legs and belly are clothed with soft white fur. In its general manner and habits this species is said to resemble the common Hedgehog. The **EARLESS HEDGEHOG** appears to be only

a variety of the common species: the head, however, is somewhat shorter and the snout more blunt; there is no appearance of external ears; it is shorter; and the whole animal is of a whitish hue.

HEDGE-SPARROW. [See SPARROW.]

HELAMYS, or JUMPING HARE. This animal constitutes a genus of mammalia, of the order *Rodentia*, allied to the Jerboas. The head is large, the tail long, the fore legs are very short in comparison with the hinder. They have four molars, each composed of two laminae; their lower incisors are truncated:

AFRICAN JUMPING HARE
(HELAMYS CAFFER)

the fore feet have five toes, furnished with long pointed nails; the hind feet have four toes, which are separate as far as the bones of the metatarsus, and furnished with large claws, almost resembling hoofs. The species *Helamys caffer* is pale fulvous, with a long tufted tail, black at the tip. It is as large as a rabbit, and, like it, inhabits deep burrows. Our cut exhibits one about to spring, while another is at the mouth of its burrow.

HELARCTOS. A genus of Bears found in India and the Eastern Islands. The Malay and Java Bears may be given as illustrations. [See BEAR.]

PELICINA. A genus of Mollusca, found in America and the West Indies. Some inhabit the sea, but others are terrestrial, either feeding upon trees or subsisting on the vegetable productions of the fields and gardens. The head of the animal is furnished with a proboscis and two tentacula, with eyes at the base on tubercles; foot short. The shell is of a flattened shape, mouth semicircular, closed by a horny operculum, which is formed of concentric layers, and permanently attached to the foot; outer lip thickened and reflected, inner lip spread over the body-whorl, terminating in a point. There are a great many species.

HELICONIDÆ. A family of Lepidopterous insects; in which the wings vary in shape, but are often very long and narrow, and the discoidal cell of the hind wings is always closed; the antennæ are slightly clavate; the palpi are short, and wide apart

at the base, the second joint being generally clothed with hairs directed upwards at its extremity. The caterpillars are cylindrical, and either spinose or furnished with several pairs of long fleshy appendages; and the chrysalides are often ornamented with brilliant golden spots. The species belonging to this family are entirely exotic, of a moderately large size, and of very varied colours. In some of the species the wings are quite denuded of scales and in many they are but slightly covered. One of the species, *Euplexa* (*Danaüs*) *hamata*, is said to be so abundant in New Holland, that it occasionally darkens the air from the clouds of them. By many authors this and the allied genera are placed in the separate family *Danaidae*. We must refer our readers to Mr. Doubleday's elaborate letter-press to his work on the Diurnal Lepidoptera, so beautifully illustrated by Mr. Hewitson.

HELICITIS. A genus of carnivorous Quadrupeds allied to the Skunks, of which there are at least two species, one found in China, where it was discovered by Mr. Reeves, the other in Nepal, whence it was sent by Mr. Hodgson.

HELIORNIS. A genus of Birds found in South America. [See *FINFOOT*.]

HELIX; HELICIDÆ. The general name of a large and most extensively diffused class of Molluscous animals with a shelly covering. It is equally adapted to the hottest and the coldest climates, the most cultivated and the most barren situations. In the Cuvierian system this is the type of a family of terrestrial and air-breathing Gastropods. The common Garden Snail of this country, and the Edible Snail of France and Italy, are well known examples of this family; but in tropical climates more striking ones are to be found. The work of Dr. Pfeiffer is the latest and the most elaborate on this group. In the works of Wood, Sowerby, Reclve and others, a great number of species are figured. An inspection of the cases containing them in the British Museum will show how varied their forms are, and how beautifully coloured are many of the species. There are some brought from the Philippine Islands by Mr. Cuming, which when wetted lose their colour, but regain it when dry. This is owing to the nature of the epidermis. [See *SNAIL*.]

HELMET-SHELL. (*Cassia*). A family of shells, of which there are several species, mostly found on tropical shores, but some

HELMET-SHELL. — (*CASSIA DECUSSATA*)

are also met with in the Mediterranean. They are inhabited by molluscous animals, some of which grow to a very large size, requiring of course a corresponding magnitude of shell. They live at some distance from

the shore, on the sand, into which they occasionally burrow, so as to hide themselves. The back of the Helmet-shell is convex, and the under part flat: the mouth is long and narrow: the lip is strongly serrated, and rises into a high thick border or ledge on the back; and the pillar is generally strongly toothed, and beset with small asperities. The shells of the *Cassia rufa* and other species are beautifully sculptured by Italian artists in imitation of antique cameos, the different layers of colouring matter resembling the onyx and other precious stones formerly used for this purpose.

Upon this subject some interesting particulars were detailed by Mr. J. E. Gray, at a meeting of the Society of Arts, held April 21. 1847. He observed that numerous attempts have been made to substitute various materials, such as porcelain and glass, for the ancient cameos; but their great inferiority has caused them to be neglected. The best and now most used substitutes are shells; several kinds of which afford the necessary difference of colour, and at the same time are soft enough to be worked with ease and hard enough to resist wear. The shells used are those of the flesh-eating univalves, which are peculiar as being formed of three layers of calcareous matters, each layer being a perpendicular lamina placed side by side. The cameo cutter selects those shells which have the three layers composed of different colours, as they afford him the means of relieving his work; but the kinds now employed, and which experience has taught him are best for his purpose, are the Bull's Mouth (*Cassia rufa*) from the Indian Seas, the Black Helmet (*Cassia Madagascariensis*), a West Indian shell, the Horned Helmet (*Cassia cornuta*), from Madagascar, and the Queen Conch (*Strombus gigas*), a native of the West Indies. The two first are the best shells. After detailing the peculiarities of these shells, Mr. Gray proceeded to give an account of the progress of the art, which was confined to Rome for upwards of forty years, and to Italy until the last twenty years, at which period an Italian commenced the making of them in Paris; and now about three hundred persons are employed in this branch of trade in that city. The number of shells used annually thirty years ago was about three hundred, the whole of which were sent from England; the value of each shell in Rome being 30s. To show the increase of this trade, the number of shells used in France last year was nearly as follows:

		Average Price.	Value.
Bull's Mouth	- 80,000	1s. 8d.	£6,400
Black Helmet	- 8,000	5s.	1,800
Horned Helmet	- 500	2s. 6d.	60
Queen Conch	- 1,200	1s. 2½d.	700

100,500 shells. Value 8,960

The average value of the large cameos made in Paris is about six francs each, giving a sterling value of 32,000l., and the value of the small cameos is about 8,000l., giving a total value of the cameos produced in Paris for

the last year of 40,000*l.*, while in England not more than six persons are employed in this trade. *Athenæum*, May 1. 1847.

HELOPIDÆ. A family of insects belonging to the order *Coleoptera*, division *Heteromera*, in which the antennæ are inserted near the eyes, and the terminal joint is always the longest, covered at the base by

HELOPS PICTUS

the margin of the head, filiform, or slightly thickened at the tip, elytra not soldered together; maxillary palpi, with the last joint largest, hatchet-shaped; eyes generally kidney-shaped. The larvæ generally filiform, with smooth shining bodies and very short feet. They are found in old wood, while the perfect insects are frequently found upon flowers, or below the bark of trees. This family consists of several genera, most of which are exotic. Mr. Paget, of Yarmouth, in his *Natural History* of that town, mentions that the larva of the common *Helops violaceus* injured the wood of a window-frame very much, in which several of these insects had taken up their abode.

HEMEROBIIUS: HEMEROBIDÆ. LACE-WING FLIES. A genus and family of insects belonging to the order *Neuroptera*; remarkable for the exceeding brilliancy of the eyes in most of the species, and for the

LACE-WING FLY—(HEMEROBIIUS.)

delicate structure and varied colours of their long reticulated wings; so that, although of small size, they are very conspicuous. They deposit their eggs upon plants, attaching them at the extremity of a long slender foot-stalk, the base of which is fastened to the leaf: thus fixed in small clusters, they have the appearance of minute fungi. The larvæ of these insects are extremely ravenous; and, as they feed on the *Aphides*, or plant-lice, are highly beneficial. During the summer they arrive at their full growth in about fifteen days; they then spin a silken cocoon, in which they enter as inactive pupæ, and there remain during the winter.

HEMIDACTYLUS. A genus of Lizards belonging to the *Gecko* family, in which

the tail is depressed, angular above, with cross rows of spines, the toes being free. The species are found in various parts of the world, and will be found described in Mr. Gray's *Catalogue of Reptiles*; one species seems to be common on the shores of the Mediterranean.

HEMIPODIUS. A genus of Gallinaceous Birds allied to the Quails, of which there are very many species in Africa and Asia chiefly. Colonel Sykes has described many of the East India species. We must refer to Gray's and Mitchell's *Genera of Birds* for a list of the species and figures of the form, and limit ourselves to the notice of a species figured in the work of Mr. Gould, where it is called the SWIFT-FLYING HEMIPODE. This bird inhabits New South Wales, and is the "Little Quail" of the colonists. The male is little more than half the size of the female. It breeds in September and October: the nest is slightly constructed of grasses, placed in a shallow depression of the ground, under the shelter of a small tuft of grass; eggs four in number. The Hemipodius lies so close as to be nearly trodden on before it will rise, and, when flushed, flies off with such rapidity as to make it very difficult to shoot.

HEMIPTERA. An order of Insects characterized by having a horny beak for suction; four wings, whereof the uppermost are generally thick at the base, with thinner extremities, which lie flat, and cross each other on the top of the back, or are of uniform thickness throughout, and slope at the sides like a roof. Transformation partial. Larvæ and pupæ nearly like the adult insect, but wanting wings.—The various kinds of field and house bugs give out a strong and disagreeable smell. Many of them (some *Pentatomidæ* and *Lygæidæ*, *Cimicidæ*, *Reduviæ*, *Hydrometridæ*, *Neptidæ*, and *Notonectidæ*) live entirely on the juices of animals, and by this means destroy great numbers of noxious insects; some are of much service in the arts, affording us the costly cochineal, scarlet grain, lac, and manna; but the benefits derived from these are more than counterbalanced by the injuries committed by the domestic kinds, and by the numerous tribes of plant-bugs, locusts or cicadæ, tree-hoppers, plant-lice, bark lice, mealy bugs, and the like, that suck the juices of plants, and require the greatest care and watchfulness on our part to keep them in check. The works of Burmeister, Amyot, and Serville, Meyer, Hutton and others may be referred to for the species, which are very numerous, and often most beautifully coloured, the colour and odour being by no means in harmony.

HEN. The general name of the female among the feathered tribes, but more especially applied to the female of the gallinaceous kind.

HEN-HARRIER. (*Circus cyaneus*.) This bird is a species of hawk; about eighteen inches in length, and three feet in extent from the tips of the wings extended. The bill is black, and covered at the base with

long bristly feathers; cere, irides, and edges of the eyelids, yellow: the upper parts of the plumage bluish gray, mixed with light tinges of rusty; the breast and under-coverts of the wings white, the former streaked with reddish brown, and the latter marked with bars of the same: the wings and tail are a bluish-gray, variegated with black; and the legs are long, slender, and yellow. The Hen-Harrier feeds on birds and reptiles; it flies low, skimming along the surface of the ground in search of prey, and is extremely destructive to young poultry and the feathered game. It makes its nest on the ground, and lays four eggs of a reddish colour, with a few white spots.

HEPATUS. A beautiful genus of Crustacea found in South America, and so named from its liver-coloured marking. The genus is allied to *Calappa*, and belongs to the same family.

HEPIALIDÆ. A family of Lepidopterous insects, in the section *HETEROCERA* (corresponding with the first group of Latreille's *NOCTURNA*). It is distinguished by having the antennæ very short and filiform, never feathered to the tip; the spiral tongue either very short or obsolete; and the palpi also generally obsolete; the wings elongated, and deflexed in repose; the abdomen also elongated, its extremity being attenuated into a long ovipositor, capable of being withdrawn, or introduced into the crevices of the bark of trees, &c. The caterpillars are sixteen-footed fleshy grubs; and feed upon the roots of vegetables or the wood of standing trees: when full grown, they construct a cocoon of the refuse of what they have been feeding upon. The chrysalis is armed with transverse rows of fine reflexed spines on the abdominal segments, which assist the insect whilst making its efforts to emerge from its confinement and assume the perfect state. The *Hepialidæ* are called *Swifts*, from the rapidity of their flight, which takes place during the twilight. Some of the species are very remarkable, particularly *HEPIALUS VIRESCENS*, a large species from New Zealand, described by Mr. Doubleday. The caterpillar of this is very frequently attacked by a fungus; which entirely converts it into a vegetable substance, the fructification and its pedicel projecting considerably. This fungus is the *Sphæria Roberti* of Hooker (*S. curcaram* of Mulsant.) Among the most striking *Hepialidæ* of this country are *Hepialus Hamuli*, or the Ghost Moth, and *Cossus ligniperda*, or the Goat Moth [which see].

HEPIOLUS. [See GHOST-MOTH.]

HERMIT CRAB. The name given to different species of the family *Paguridæ*, which occupy empty shells, in which they protect their soft and otherwise easily injured tails. [See CRAB: *PAGURUS*.]

HERON. (*Ardea*.) Though birds of the crane, the stork, and the Heron kind, have a strong affinity to each other, the Heron may be distinguished by its smaller size, its longer bill, and particularly by the middle

claw on each foot, which is serrated, for the better seizing and securing its slippery prey. Herons reside on the banks of lakes and rivers, or in marshy places: their food consists of fishes and their fry, frogs, and field mice, as well as all sorts of insects, snails, and worms. They build in large societies in the same place; and when they fly, their neck is contracted and folded over their back, and their legs are extended.

The COMMON HERON (*Ardea cinerea*) is remarkably light in proportion to its bulk, scarcely weighing three pounds and a half, though its length is upwards of three feet, and its extended breadth above five. The bill is six inches long, straight, pointed, and strong; the upper mandible is of a yellowish horn colour, the under one yellow: the forehead, neck, middle of the belly, edge of the wing, and the thighs, are of a pure white; the occiput, the sides of the breast, and those of the body, of a deep black: the fore part of the neck is adorned with large longitudinal spots of black and gray; the back and wings are blue gray. A bare greenish skin is extended from the beak beyond the eyes, the irides of which are yellow, giving them a fierce and piercing aspect. The back part of the head is ornamented with several elongated narrow black feathers, the two middle of which are upwards of eight inches in length; the whole forming an elegant pendent crest; the feathers of the scapulars are also elongated, and fall over the back in fine disunited plumes. The tail is composed of twelve short cinereous feathers; the legs are of a dirty green colour, long, and bare above the knees; and the inner edge of the middle claw is finely serrated. The female is destitute of the long crest of the male, having only a short plume of dusky feathers; and in general her plumage is gray: the same remarks are also nearly applicable to the young birds. In the breeding season they congregate in large societies, and, like the rooks, build their nests on trees, with sticks, lined with dried grass, wool, and other warm materials. The female lays from four to six eggs, of a pale greenish blue colour.

This bird commits great devastation in ponds and shallow waters. As a proof of its appetite, it is asserted by Willoughby and others, that a single Heron will destroy fifty small roach and dace, one day with another. Though it generally takes its prey by wading into the water, and waiting patiently for its approach, it frequently also catches it whilst on the wing; but this is only in shallow waters, where it is able to dart with more certainty than in the deep; for in this case, though the fish does at the first sight of its enemy descend, yet the bird, with its long beak and legs, instantly plies it to the bottom, and there seizes it securely. In general, the Heron is seen taking his gloomy stand by the side of a lake, as if meditating mischief, motionless, and gorged with plunder. His usual attitude on such occasions is that of sinking his long neck between his shoulders, and keeping his head turned on one side, as if viewing the water more intently. When the call of hunger returns,

the toil of an hour or two is sufficient to fill his capacious stomach; and, though he often feeds by night, he generally is able to retire long before to his lodging in some wood, which he quits early next morning. But in cold and stormy seasons, when his prey is no longer within his reach—the fish then abiding in the deep as their warmest situation, and frogs, lizards, and other reptiles, also seldom venturing from their retreats during the continuance of such weather—the Heron is obliged to practise abstinence, and to feed on such weeds as the margin of the lake affords: hence he feels the ill both of hunger and repletion, and notwithstanding the amazing quantity he devours, he is always lean and emaciated. While on this subject, it may, however, be well to attend to what Mr. Waterton has written: "I attribute the bad character (says he) which the Heron has with us, for destroying fish, more to erroneous ideas, than to any well-authenticated proofs that it commits extensive depredations on our store-ponds. Under this impression, which certainly hitherto has not been to my disadvantage, I encourage this poor persecuted wader to come and take shelter here; and I am glad to see it build its nest in the trees which overhang the water, though carp, and tench, and many other sorts of fish are there in abundance. Close attention to its habits has convinced me that I have not done wrongly. Let us bear in mind that the Heron can neither swim nor dive; wherefore the range of its depredations on the finny tribe must necessarily be very circumscribed. In the shallow water only can it surprise the fish; and, even there, when we see it standing motionless, and suppose it to be intent on striking some delicious perch or passing tench, it is just as likely that it has waded into the pond to have a better opportunity of transfixing a water-rat lurking at the mouth of its hole, or of gobbling down some unfortunate frog which had taken refuge on the rush-grown margin of the pool. The water-rat may appear a large morsel to be swallowed whole; but so great are the expansive powers of the Heron's throat, that it can gulp down one of these animals without much apparent difficulty. As the ordinary food of this bird consists of reptiles, quadrupeds, and fish, and as the Herons can only catch the fish when they come into shallow water, I think we may fairly consider this wader not very injurious to our property; especially when we reflect for a moment on the prodigious fecundity of fish."

In its aerial journey the Heron soars to a great height, and its harsh cry while on the wing frequently attracts the ear. In flying, it draws the head between the shoulders, and the legs, stretched out, seem, like the longer tails of some birds, to serve as a rudder. The motion of their wings is heavy and flapping, and yet they proceed at a very considerable rate. In England, Heron-hawking was formerly a favourite diversion among the nobility and gentry of the kingdom, at whose tables this bird was a favourite dish, not less esteemed than pheasants and peacocks. It was ranked among the

royal game, and protected as such by the laws; and a penalty of twenty shillings was incurred by any person who took or destroyed its eggs.—Dr. Latham says, "In England, and the milder climates, this species of Heron is stationary; migratory in the colder, according to the season; and is rarely seen far north: inhabits Africa and Asia in general, the Cape of Good Hope, Calcutta, and other parts of India; and is found in America from Carolina to New York."

THE AGAMI HERON. (*Ardea Agami*.) By general consent, as it were, this bird is allowed to be the most beautiful of the genus. It is a native of Surinam, and is rather more than two feet and a half in length: its beak is about six inches long, and dusky, with the base of the under mandible pale; the crown, the crest, and the hind part of the neck are bluish gray; the upper parts of the body, the wings, and the tail, are a fine glossy green; the quills are black; the sides of the neck bright rufous, with an elegant white and rufous line, bounded by black down the central part; the breast is clothed with long, loose, dark feathers; those on the back of the neck black, with a white streak down the middle of each shaft; the under parts of the body are deep rufous; and the tail is brown.

THE GREAT HERON. (*Ardea Herodias*.) This species inhabits North America, and is one of the largest of the genus, measuring upwards of five feet in length; the beak is eight inches long, and of a brown colour, inclining to yellow on the sides; on the back of the head is a long-feathered crest;

GREAT HERON.—(*ARDEA HERODIAS*.)

the space between the beak and eye is naked, and of a pale yellow; all the upper parts of the body, with the belly, tail, and legs, are brown; the quills black; the neck, breast, and thighs rufous. Like the rest of this

geus, the Great Heron frequents the borders of lakes and rivers, and feeds on reptiles and small fishes.

THE GREAT WHITE HERON. (*Herodias alba*.) This bird's plumage is wholly white; it may therefore be easily known from the common Heron: it is also rather smaller, the tail and legs are longer, and it has no crest. Its character and manner of living are the same, and it is found in the same countries, though the species is far less numerous, and it is rarely seen in Great Britain. It is found on the shores of the Caspian and Black Seas, the lakes of Great Tartary, and sometimes even much farther north: it is also met with in various parts of Africa and America.

THE LITTLE EGRET HERON (*Herodias garzetta*) is one of the most elegant as well as one of the smallest of the Heron tribe. The beak is black, the naked space round the eyes greenish, the legs dusky, and the feet black. Its colour is of the purest white, and it is adorned with soft, silky, flowing plumes on the head, breast, and shoulders, which give the bird a beauty quite peculiar to itself. These delicately-formed feathers are six or eight inches in length, with slender shafts, twisted and bent down towards their tips: they were formerly used to decorate the helmets of warriors, but they now embellish the turbans of Turks and Persians, or are applied to the more consistent purpose of ornamenting the head-dresses of European ladies. The Little Egret is only about eighteen inches in length, and seldom exceeds a pound and a half in weight. These birds are said to have once been plentiful in this country, but they are now nearly extinct here; they are, however, abundant in the south of Europe, and are found in almost every temperate and warm climate. Like the Common Heron, they perch and build on trees, and live on the same kinds of food.

THE NIGHT HERON. (*Nycticorax griseus*.) This species, which with its congeners is placed by modern naturalists in a separate genus (*Nycticorax*), is by no means numerous, though widely dispersed over Europe, Asia, and America. It is about twenty inches in length: the bill is slightly arched, strong, and black, inclining to yellow at the base: from the beak round the eyes the skin is bare and of a greenish colour: over each eye is a white line; a black patch, glossed with green, covers the crown of the head and the nape of the neck, from which three long narrow white feathers, tipped with brown, hang loose and waving. The hinder part of the neck, coverts of the wings, the sides, and tail, are ash gray; throat white; fore part of the neck, breast, and belly, yellowish white or buff; the back black; legs greenish yellow. The plumage of the female is considerably less bright and distinct; and she has none of the delicate plumes which flow from the head of the male. She lays three or four white eggs. The Night Heron frequents the sea-shores, rivers, and inland marshes, and lives upon insects, slugs, reptiles, and fish. It remains concealed during the day, and does not roam abroad until the

approach of night, when its harsh and disagreeable cry is painfully distinguishable. It builds its nest on trees and on rocky cliffs.

There are numerous other species and varieties of the Heron, differing in their size and plumage, but nearly all having the same habits, and being characterized by similar features with those we have described. Among the most important are the Purple-crested Heron (*Ardea purpurea*), common in the western parts of Asia and the north of Europe; the Violet Heron (*Ardea leucophaea*) of the East Indies; the Cooi Heron (*Ardea cooi*), a large species, native of Brazil; the Little White Heron (*Ardea Equinoctialis*), a native of Carolina and some other parts of North America; besides the Blue, the Brown, the Black, the Ash-coloured Heron, &c.

In Mr. Edwards's narrative of a "Voyage up the Amazon," one cannot but be struck with the multitudes of large birds which almost everywhere met the eye of the voyager; not the least numerous or important among them being various species of Herons. "Upon the trees," says he, "were perched birds of every variety, which flew before our advance at short distances in constantly increasing numbers, or, curving, passed directly over us; in either case affording marks too tempting to be neglected. Upon some topmost limb the great blue Heron, elsewhere shyest of the shy, sat curiously gazing at our approach. Near him, but lower down, herons white as driven snow—some tall and majestic as river naiads, others small and the pictures of grace—were quietly dozing after their morning's meal. Multitudes of night herons, or tacarés, with a loud quack, flew startled by; and now and then, but rarely, a boat-bill with his long-plumed crest would scud before us. The snake-bird peered out his long neck to discover the cause of the general commotion; the cormorant dove, from the dry stick where he had slept away the last hour, into the water below, swimming with head scarcely visible above the surface, and a ready eye to a treacherous shot. Ducks rose hurriedly, and whistled away; curassows flew timidly to the deeper wood; and fearless hawks, of many varieties, looked boldly on the danger."

HERRING. (*Clupea Harengus*.) This Malacopterygious fish, which frequents our coasts in such numbers, and furnishes a large class of persons with an important article of food, is from ten to twelve inches in length. It is principally distinguished by the brilliant silvery colour of its body, the advance-

HERRING.—(CLUPEA HARENGUS.)

ment of the lower jaw beyond the upper, and by the number of rays in the anal fin, which are generally found to amount to sixteen: the back and sides are green, varied with

blue; the eyes are large; the mouth without visible teeth; the openings of the gill-covers very large; the scales moderate in size, oval, and thin; the lateral line not very distinctly visible; the belly carinated, but not serrated; the fins rather small than large for the size of the fish; and the tail considerably forked.

It has long been asserted, and generally believed, that Herrings are found in the greatest abundance in the high northern latitudes; and that the prodigious shoals which at certain seasons fill our seas, are making their migratory excursions from those icy regions. But this "great fact" in natural history has not only been called in question of late, but the migration of the Herring from one latitude to another has been denied by men of high scientific attainments who have given the subject great attention, and who assert that the Herring, having passed the winter and spring months in the deep recesses of the ocean, follows the dictates of nature, and at the proper season approaches the shallower water near the coasts to deposit its spawn. We shall therefore lay the statements, *pro* and *con*, before our readers.

Mr. Pennant, in his *British Zoology*, says, "The great winter rendezvous of the Herring is within the arctic circle: there they continue many months, in order to recruit themselves after the fatigue of spawning, the seas within that space swarming with small crustacea in a far greater degree than in our warmer latitudes." He then thus proceeds: "This mighty army begins to put itself in motion in the spring: we distinguish this vast body by that name, for the word Herring is derived from the German, *Heer*, an army, to express their numbers. They begin to appear off the Shetland Isles in April and May: these are only forerunners of the grand shoal which comes in June, and their appearance is marked by certain signs, by the numbers of birds, such as gannets and others, which follow to prey on them: but when the main body approaches, its breadth and depth is such as to alter the very appearance of the ocean. It is divided into distinct columns of five or six miles in length and three or four in breadth, and they drive the water before them with a kind of rippling: sometimes they sink for the space of ten or fifteen minutes; then rise again to the surface, and in bright weather reflect a variety of splendid colours, like a field of the most precious gems, in which, or rather in a much more valuable light, should this stupendous gift of Providence be considered by the inhabitants of the British Isles. The first check this army meets in its march southward, is from the Shetland Isles, which divide it into two parts; one wing takes to the east, the other to the western shores of Great Britain, and fill every bay and creek with their numbers: others pass on towards Yarmouth, the great and ancient mart of Herrings: they then pass through the British Channel, and after that in a manner disappear: those which take to the west, after offering themselves to the Hebrides, where the great stationary fishery is, proceed towards the north of Ire-

land, where they meet with a second interruption, and are obliged to make a second division: the one takes to the western side, and is scarce perceived, being soon lost in the immensity of the Atlantic; but the other, which passes into the Irish sea, rejoices and feeds the inhabitants of the coasts that border it. These brigades, as we may call them, which are thus separated from the greater columns, are often capricious in their movements, and do not show an invariable attachment to their haunts."

The foregoing account, so well detailed by Pennant, was until lately, as we have before remarked, the generally received opinion; but it is now supposed that the Herring, like the Mackerel, is in reality at no very great distance during the winter months from the shores which it most frequents at the commencement of the spawning season; and this is thought a sufficient explanation of the glittering myriads which at particular seasons illumine the surface of the ocean for miles together. As a proof of this, Dr. Bloch observes that Herrings are in reality found at almost all seasons of the year about some of the European coasts, and that the northern voyages, supposed by Pennant and others, are impracticable in the short period assigned by naturalists; the fish, in its swiftest progress, being utterly incapable of moving at so rapid a rate as this migration necessarily supposes.

But the subject has been more amply discussed by Mr. Yarrell, who brings forward so many valid and well-supported objections to the theory of the Herring's migration from the arctic seas, that we shall take the liberty of extracting them from his excellent work. "To show that this supposed migration to and from high northern latitudes does not exist, it is only necessary to state, that the Herring has never been noticed, that I am aware, as abounding in the Arctic Ocean: it has not been observed in any number in the proper icy seas; nor have our whale-fishers or arctic voyagers taken any particular notice of them. There is no fishery for them of any consequence either in Greenland or Iceland. On the southern coast of Greenland the Herring is a rare fish; and only a small variety of it, according to Crantz, is found on the northern shore. This small variety or species was found by Sir John Franklin, on the shore of the Polar basin, on his second journey. 'That the Herring is, to a certain degree, a migratory fish,' says Dr. McCulloch, 'may be true; but even a much more limited migration is far from demonstrable. It is at any rate perfectly certain that there is no such progress along the east and west coasts from a central point.' There can be no doubt that the Herring inhabits the deep water all round our coast, and only approaches the shores for the purpose of depositing its spawn within the immediate influence of the two principal agents in vivification—increased temperature and oxygen; and as soon as that essential operation is effected, the shoals that haunt our coast disappear: but individuals are to be found, and many are caught, throughout the year.

So far are they from being migratory to us from the North only, that Herrings visit the west coast of the county of Cork in August, which is earlier than those which come down the Irish Channel arrive, and long before they make their appearance at other places much farther north. 'In former times, the fishery on the east coast did not commence till that on the west had terminated. It is remarkable also that the eastern fishery has become so abundant as quite to have obscured the western.' And Dr. McCulloch, from other examples, confirms a statement previously made, that the fishery has commenced soonest on the southern part of the shore; and what is also remarkable, that for some years past it has become later every year. The Herring is in truth a most capricious fish, seldom remaining in one place; and there is scarcely a fishing station round the British Islands that has not experienced in the visits of this fish the greatest variations both as to time and quantity, without any accountable reason."

Herrings are full of roe in the end of June, and continue in perfection till the beginning of winter, when they deposit their spawn. The young Herrings begin to approach the shores in July and August, and are then from half an inch to two inches long. The Herring was unknown to the ancients, being rarely, if ever, found within the Mediterranean. The Dutch are said to have engaged in the fishery in 1184. The invention of pickling or salting Herrings is ascribed to one Benckels, or Benckelson, of Blervillet, near Sluys, who died in 1397. The emperor Charles V. visited his grave, and ordered a magnificent tomb to be erected to his memory. Since this early period the Dutch have uniformly maintained their ascendancy in the Herring fishery; but, owing to the Reformation, and the relaxed observance of Lent in Roman Catholic countries, the demand for Herrings upon the Continent is now far less than in the fourteenth and fifteenth centuries. The mode of fishing for Herrings is by drift-nets, very similar to those employed in the pilchard fisheries: the fishing is carried on only in the night; the most favourable time being when it is quite dark, and the surface of the water is ruffled by a breeze.

Though there are some other species of Herrings, none of them are of the same commercial importance as the Common Herring, already described, which so abundantly visits our shores; a slight notice of one of them, therefore, is all that will be necessary.

LEACH'S HERRING. (*Clupea Leachii*.) "The Herring," says Mr. Yarrell, "which I now refer to, is found heavy with roe at the end of January, which it does not deposit till the middle of February. Its length is not more than seven inches and a half, and its depth near two inches. It is known that Dr. Leach had often stated that our coast produced a second species of Herring; but I am not aware that any notice of it has ever appeared in print. In order, however, to identify the name of that distinguished naturalist with a fish of which he was pro-

bably the first observer, I proposed for it the name of *Clupea Leachii*." The flesh of this species is said to differ from that of the Common Herring in flavour, and to be much more mild.

HESPERIIDÆ. A family of Lepidopterous insects, corresponding with the *Plebeii Urbicoli* of Linnæus, and in many respects approaching to the Moths. The six feet are of uniform size in both sexes, the hind tibia having a pair of spurs at the apex, and another pair near the middle of the limb; the antennæ are wide apart at the base, and are often terminated in a very strong hook; the maxillæ are very long; and the lower wings are generally horizontal during repose. All the known caterpillars belonging to this family are cylindrical without spines, with the anterior segments narrowed, and the head very large: they roll up leaves, in which they construct a slight silken cocoon, wherein the chrysalis form is assumed; this is entire, without angular prominences, and attached by the tail as well as girt round the middle.

These Butterflies have a peculiar, short, jerking kind of flight, which has obtained for them the name of *Skippers*. The species

HESPERIA [PAMPHILA] SYLVANUS, M.

are of comparatively small size, and of obscure colours, but some are ornamented with bright transparent spots, and others have

HESPERIA [PAMPHILA] SYLVANUS, F.

the hind wings furnished with long tails. They have a robust body; and frequently settle on flowers, leaves, and branches. There are a few British species, descriptions of which will be found in the works of Stephens and Humphreys. The "Genera of Diurnal Lepidoptera" of Doubleday and Hewitson will be found to contain much information on this family, which in foreign countries abounds in species and genera.

Hessian FLY. (*Cecidomyia destructor*.) This far-famed fly, as well as the "wheat-fly, which are common both to Europe and America, are small gnats or midges, and belong to the family called *Cecidomyiadae*, or gall-gnats. The insects of this family are very numerous, and most of them, in the maggot state, live in galls or unnatural en-

largements of the stems, leaves, and buds of plants, caused by the punctures of the winged insects in laying their eggs. The Hessian fly, wheat-fly, and some others differ from the majority in not producing such alterations in plants. The proboscis of these insects is very short, and does not contain the piercing bistles found in the long proboscis of the biting gnats and mosquitoes. Their antennæ are long, composed of many little bead-like joints, which are larger in the males than in the females; and each joint is surrounded with short hairs. Their eyes are kidney-shaped. Their legs are rather long and very slender. Their wings have only two, three, or four veins in them, and are fringed with little hairs around the edges; when not in use, they are generally carried flat on the back. The hind body of the female often ends with a retractile, conical tube, wherewith they deposit their eggs. Their young are little footless maggots, tapering at each end, and generally of a deep yellow or orange colour. They live on the juices of plants, and undergo their transformations either in these plants or in the ground.

The Hessian fly obtained its common name from a supposition that it was imported into England from Germany, and taken to North America in some straw, by the Hessian troops under the command of Sir W. Howe, in the war of the Revolution. This supposition, however, has been thought to be erroneous, because the early inquiries made to discover the Hessian fly in Germany were unsuccessful. Dr. Thaddeus Harris brings together, with much industry, a large amount of information from various sources relative to its economy, its habits, and transformations; and from his statement we shall endeavour to lay the principal facts before our readers. The head and thorax of this fly are black. The hind body is tawny, and covered with fine grayish hairs. The wings are blackish, but are more or less tinged with yellow at the base, where also they are very narrow; they are fringed with short hairs, and are rounded at the end. The body measures about one-tenth of an inch in length, and the wings expand one quarter of an inch or more. Two broods or generations are brought to maturity in the course of a year, and the flies appear in the spring and autumn. It has frequently been asserted that the flies lay their eggs on the grains in the ear; but whether this be true or not, it is certain that they do lay their eggs on the young plants, and long before the grain is ripe. The egg is about the fiftieth of an inch long, and four thousandths of an inch in diameter, cylindrical, translucent, and of a pale red colour. The maggots, when they first come out of the shells, are of a pale red colour. Forthwith they crawl down the leaf, and work their way between it and the main stalk, passing downwards till they come to a joint, just above which they remain, a little below the surface of the ground, with the head towards the root of the plant. Having thus fixed themselves upon the stalk, they become stationary, and never move from the place till their transformations are completed. They do not eat the stalk, neither

do they penetrate within it, as some persons have supposed, but they lie lengthwise upon its surface, covered by the lower part of the leaves, and are nourished wholly by the sap, which they appear to take by suction. They soon lose their reddish colour, turn pale, and will be found to be clouded with whitish spots; and through their transparent skins a greenish stripe may be seen in the middle of their bodies. As they increase in size, and grow plump and firm, they become imbedded in the side of the stem, by the pressure of their bodies upon the growing plant; but when two or three are fixed in this manner around the stem, they weaken and impoverish the plant, and cause it to fall down, or to wither and die. They usually come to their full size in five or six weeks, and then measure about three-twentieths of an inch in length. Their skin now gradually hardens, becomes brownish, and soon changes to a bright chestnut colour. This change usually happens about the first of December, when the insect may be said to enter on the pupa state, for after this time it takes no more nourishment. The brown and leathery skin, within which the maggot has changed to a pupa or chrysalis, is long, egg-shaped, smooth, and marked with eleven transverse lines, and measures one-eighth of an inch in length. In this form it has been commonly likened to a flax-seed. It appears, then, from the remarks of the most careful observers that the maggots of the Hessian fly do not cast off their skins in order to become pupæ, wherein they differ from the larvæ of most other gnats, and agree with those of common flies; neither do they spin cocoons, as some of the Cecidomyiæ are supposed to do. Inclosed within the dried skin of the larva, which thus becomes a kind of cocoon or shell for the pupa, it remains throughout the winter, safely lodged in its bed on the side of the stem, near the root of the plant; and protected from the cold by the dead leaves.

Very soon after the flies come forth in the spring, they are prepared to lay their eggs on the leaves of the wheat sown in the autumn before, and also on the spring-sown wheat, that begins, at this time, to appear above the surface of the ground. They continue to come forth and lay their eggs for the space of three weeks, after which they entirely disappear from the fields. The maggots, hatched from these eggs, pass along the stems of the wheat, nearly to the roots, become stationary, and turn to pupæ in June and July. In this state they are found at the time of harvest, and, when the grain is gathered, they remain in the stubble in the fields. To this there are, however, a few exceptions; for a few of the insects do not pass so far down the side of the stems as to be out of the way of the sickle when the grain is reaped, and consequently will be gathered and carried away with the straw; and from this circumstance it is possible that they might have been imported in straw from a foreign country. In the winged state, these flies, or more properly gnats, are very active, and, though very small and seemingly feeble, are able to fly to a considerable distance in search of fields of young grain.

The best modes of preventing the ravages of the Hessian fly are thus stated by Mr. Herrick, in the 'American Journal of Science,' vol. 41. "The stouter varieties of wheat ought always to be chosen, and the land should be kept in good condition. If full wheat is sown late, some of the eggs will be avoided, but risk of winter killing the plants will be incurred. If cattle are permitted to graze the wheat fields during the fall, they will devour many of the eggs. A large number of the pupæ may be destroyed by burning the wheat stubble immediately after harvest, and then ploughing and harrowing the land. This method will undoubtedly do much good. As the Hessian fly also lays its eggs, to some extent, on rye and barley, these crops should be treated in a similar manner." It is found that luxuriant crops more often escape injury than those that are thin and light. Steeping the grain and rolling it in plaster or lime tends to promote a rapid and vigorous growth, and will therefore prove beneficial. Sowing the fields with wood ashes, in the proportion of two bushels to an acre, in the autumn, and again in the first and last weeks in April, and as late in the month of May as the sower can pass over the wheat without injury to it, has been found useful. Favourable reports have been made upon the practice of allowing sheep to feed off the crop late in the autumn, and it has also been recommended to turn them into the fields again in the spring, in order to retard the growth of the plant till after the fly has disappeared. Too much cannot be said in favour of a judicious management of the soil, feeding off the crop by cattle in the autumn, and burning the stubble after harvest; which will materially lessen the evils arising from the depredations of this noxious insect. Mr. Hardy has described and given the history of the British species.

HETEROCERA. A section of *Lepidoptera*, agreeing with the Linnean genera *Sphinx* and *Phalæna*. It derives its name from the diversified formation of the antennæ, which are never terminated by a club, like those of the butterflies, but are generally setaceous, filiform, or fosiform, those of the males being moreover often furnished with lateral appendages, forming branches. The caterpillars are much varied, but the pupæ are generally of a conical form, and are ordinarily enclosed in a cocoon, the quiescent state being often undergone in the ground. Modern entomologists have found much difficulty in defining the various groups which compose the *Crepuscularia* and *Nocturna*, and our space precludes us from entering at large upon any subject where much uncertainty exists; nor, indeed, is it essential that we should do so. Mr. Westwood observes, that "*Urania*, *Castnia*, *Agarista*, *Sphinx*, *Egeria*, and *Anthrocera* are groups of equal value among themselves; and on account of the peculiar conformation of their antennæ, they were united into one group by Linnaeus, who, it is well known, considered this character as of the highest importance. Take, for instance, the three

English groups, *Sphinx*, *Egeria*, and *Anthrocera*, and we find the first isolated: the second, in its fenestrated wings, approaches some of the *Sphingide*, but its metamorphoses are totally different, resembling those of *Cossus*; whilst *Anthrocera*, on the other hand, is, in its preparatory states, a *Bombyx*, and in its final one probably intermediate between *Macroglossa* and *Pyrallis*; *Egeria*, nevertheless, is not farther removed from *Sphinx* than is *Castnia* or *Urania*, nor than *Hepialus* or *Lithosia* are from *Attacus*, in the tribe of *Bombycidae*. *Geometra*, *Tortrix*, *Noctua*, &c., in their extended state, are groups admirably defined, and yet it is impossible to look at *Euclidia*, *Acosmetia*, *Nola*, or *Platypteryx*, without perceiving either that we must extend the limits of our families, so as to admit these anomalous groups, or create a far greater number of families than has hitherto been done" * * * "With regard to the primary groups of the *Heterocera*, I candidly admit that I am not able to offer a satisfactory classification, although it seems unquestionable that *Sphinx* (or the Hawk-moths), *Bombyx* (or the feather-horned full-bodies), *Noctua* (or the thread-horned full-bodies), *Geometra* (or the loopers), *Pyrallis*, *Tortrix*, and *Tinea*, are, as Linnaeus considered them, amongst the primary types."

HETEROCERIDÆ. A family of Coleopterous insects, of small size and subaquatic habits: body depressed; legs broad, compressed, and serrated; the thorax much narrower than the elytra; the jaws robust; and the antennæ short. These insects burrow in the mud of the banks of ponds or stagnant water, out of which they make their escape when the earth is shaken or stamped upon, and again as quickly bury themselves in the mud. Their bodies are clothed with a fine silky pubescence, whereby the action of the water upon them is prevented. They walk but slowly; yet they are sometimes observed in the hot sunshine to raise their wings, fly off, and again alight, with all the agility of the tiger-beetles. There is every reason to suppose them to be carulvorous.

HETEROMERA. A section of the Coleoptera, comprehending those beetles which have five joints in the tarsus of the first and second pairs of legs, and only four joints in the tarsus of the third pair. This division includes several extensive groups, the majority of the species of which feed upon vegetable substances: some are gaily coloured, and such are generally found in flowers; others, which frequent dark and damp places, are uniformly black: whilst those which inhabit the sandy deserts of tropical regions are of various obscure shades of gray or brown.

HETEROPODA. An order of Molluscous animals, closely allied to the *Gastropoda*, but distinguished from them and all others by the structure and position of the foot, which is compressed, so as to constitute a vertical muscular paddle, or fin. The gills are external, and form plume-like tufts,

situated at the hinder part of the back: the body is gelatinous and transparent; and the mouth is furnished with a kind of muscular tube or proboscis, and a rough tongue. In their general form and structure they correspond very closely with those of the *Carinaria*, which has a thin shell, in form not unlike that of the Argonaut. They all inhabit either the tropical seas, or those of moderately warm climates. The best known genera are *Carinaria*, *Atlanta*, and *Firola*. Figures of the shells and animals of all these will be found in the admirably useful work of Mrs. Gray, "Figures of Mollusca."

HETEROPTERA. The name given to a section of the order of insects called **HEMPTERA**, distinguished by the anterior wings being tough at their bases and membranous only towards their points. By far the greater number of them feed upon the juices of plants; some, however, prey upon smaller insects, and others suck the juices of larger animals. They chiefly inhabit tropical regions, and are mostly ornamented with beautiful colours and markings, which

RED-LEGGED PLANT BUG.
(*PENTATOMA RUFIPES*.)

often vie with the most splendid of the Beetle tribe: those, however, whose habits are aquatic, are of a black or obscure colour. Most of the terrestrial species emit a powerful odour when suddenly alarmed or touched; this is occasionally of an agreeable nature, but more commonly (as in the case of the Bug — *Cimex lectularius*) disgustingly offensive. As an example we give a cut of the *Pentatoma rufipes*, a common species in this country. [See **HEMPTERA**.]

HIMANTOPUS, or LONG-LEGGED PLOVER. A genus of Grallatorial birds, distinguished by the great length of their legs; from which circumstance they are sometimes called *Stilt-Birds*.

One species is occasionally found in this country; the **LONG-LEGGED PLOVER**, (*Himantopus candidus*, or *Charadrius Himantopus* of Linnæus.) White has recorded its appearance in the neighbourhood of his favourite Selbourne; and we believe our readers will be better pleased with the account so graphically portrayed by him in a letter to Pennant, than by any other description we perchance might offer. "In the last week of last month (April, 1799), five of these most rare birds, too uncommon to have obtained an English name, but known to naturalists by the terms *Himantopus*, *Loripes*, and *Charadrius Himantopus*, were shot upon the verge of Frinsham pond, a large lake belonging to the Bishop of Winchester, and lying between Wolmer forest and the town

of Farnham, in the county of Surrey. The pond-keeper says there were three brace in the flock; but that after he had satisfied his curiosity, he suffered the sixth to remain unmolested. One of these specimens I procured, and found the length of the legs to be so extraordinary, that, at first sight, one might have supposed the shanks had been fastened on to impose on the credulity of the beholder: they were legs in caricature; and had we seen such proportions on a Chinese or Japan screen, we should have made large allowance for the fancy of the draughtsman. These birds are of the *Plover* family, and might with propriety be called *Stilt Plovers*. Brisson, under that idea, gives them the appropriate name of *l'échasse*. My specimen, when drawn and stuffed with pepper, weighed only four ounces and a quarter, though the naked part of the thigh measured three inches and a half. Hence we may safely assert that these birds exhibit, weight for inches, incomparably the greatest length of legs of any known bird. The *flamingo*, for instance, is one of the most long-legged birds, and yet it bears no manner of proportion to the *Himantopus*; for a cock *flamingo* weighs at an average about four pounds avoirdupois: and his legs and thighs measure usually about twenty inches. But four pounds are fifteen times and a fraction more than four ounces and one quarter; and if four ounces and a quarter have eight inches of legs, four pounds must have one hundred and twenty inches and a fraction of legs, viz. somewhat more than ten feet, such a monstrous proportion as the world never saw! If you should try the experiment in still larger birds, the disparity would still increase. It must be matter of great curiosity to see the *Stilt Plover* move; to observe how it can wield such a length of lever with such feeble muscles as the thighs seem to be furnished with. At best one should expect it to be but a bad walker; but what adds to the wonder is, that it has no back toe. Now without that steady prop to support its steps, it must be liable in speculation to perpetual vacillations, and seldom able to preserve the true centre of gravity. The old name of *Himantopus* is taken from Pliny; and, by an awkward metaphor, implies that the legs are as slender and pliant as if cut out of a thong of leather. Neither Willoughby nor Ray, in all their curious researches, either at home or abroad, ever saw this bird. Mr. Pennant never met with it in all Great Britain, but observed it often in the cabinets of the curious at Paris. Hasselquist says that it migrates to Egypt in the autumn; and a most accurate observer of nature has assured me that he has found it on the banks of the streams in Andalusia. Our writers record it to have been found twice in Great Britain. From all these relations it plainly appears that the Long-legged Plovers are birds of South Europe, and rarely visit our island; and when they do, are wanderers and stragglers, and impelled to make so distant a northern excursion from motives and accidents for which we are not able to account. One thing may fairly be deduced, that these birds come over to us from the

Continent, since nobody can suppose that a species not noticed once in an age, and of such a remarkable make, can constantly breed unobserved in this kingdom.

Mr. Gould observes, in his 'Birds of Europe,' "The Long-legged Plover, as its conformation would lead us to conclude, is a bird whose most congenial habitat is morasses and the low flat shores of lakes, rivers, and seas. Hence in the eastern portions of Europe, where it is said to arrive from Asia in small flocks, it takes up its abode along the lakes and among the vast morasses of Hungary and Russia, where, according to M. Temminck, it rears its progeny, and where it fearlessly wades in search of its food, without much chance of being carried out of its depth; but should such an occurrence happen, or the waves drift it out from the shore, it possesses, like many of the true Wading Birds, the power of swimming with the greatest ease and lightness: in fact, in whatever point of view we consider the Long-legged Plover, we find it adapted in the best possible manner for its habits and modes of life. Few birds exceed it in the powers of flight; its wings far exceed the tail, and it passes through the air with astonishing rapidity. When on firm ground, it appears as if tottering on long and awkward stilts, but firm ground is not its congenial habitat."

An allied species (*H. nigricollis*) is described by Wilson, in his American Ornithology, under the same name as the European, but it is distinct. In 'Gould's Birds of Australia' three species are figured and described; two from Australia, the *H. leucocephalus* and *Cladorhynchus pectoralis*, and one from New Zealand, the *H. Novæ Zealandiæ*, so that this genus and group of Long-legged birds is very widely distributed.

HIND. The female of the Red Deer or Stag. [See DEER.]

HINULIA. A genus of Reptiles closely allied to the officinal *Scincus*, most of the species of which appear to be natives of Australia; a few species are natives of the East. Descriptions of all the species will be found in Mr. Gray's Catalogue of the Reptiles in the British Museum.

HIPPA: HIPPIDÆ. A genus and family of Anomalous Decapod Crustacea, the species of which seem to be fond of working in the sand. One species, the *H. tolpoida*, is called sand-bug in North America. To this family belong *Albunea*, *Remipes*, and *Cosmonotus*, which with *Hippa* form very striking and beautiful exotic genera.

HIPPARCHIA, or SATYRUS. A genus of Diurnal Lepidoptera, the species of which are for the most part brown or obscure. In temperate regions and in mountainous districts generally there are numerous; some being found in Lapland (*Chionobas*), and others on elevated ground within the tropics. In this country are several species, some of which are specified beneath; the other British species are recorded in the works of Stephens, Curtis, and Humphreys; while a new species to this country, found lately in

Perthshire, is figured and described in "The Zoologist." We must again refer for information to Doubleday and Hewitson's Genera of Diurnal Lepidoptera. The British species we restrict our attention to, are—

The **HIPPARCHIA GALATHEA**, or **MARbled WHITE BUTTERFLY**. This pretty Butterfly is of a yellowish white colour chequered with black, which produces a pleasing effect. In

MARbled WHITE BUTTERFLY.
(*HIPPARCHIA GALATHEA*.)

some species the black prevails; in others the yellowish-white; the female is larger than the male. It is found abundantly near London, and in most parts of England, chiefly frequenting moist meadows, where it appears in June and July. The caterpillar feeds on grass,

UNDER SIDE OF MARbled WHITE BUTTERFLY.—(*HIPPARCHIA GALATHEA*.)

particularly the *Phleum pratense*; is yellowish-green, and strikingly resembles that of some of the moths, and, like most if not all the species of the genus, feeds at night. Our figures, derived from the admirable work of

CATERPILLAR AND CHRYSALIS OF MARbled WHITE BUTTERFLY.—(*H. GALATHEA*.)

Hübner, show the upper and under sides of the perfect insect, with the caterpillar and the chrysalis.

THE HIPPARCHIA SEVELE, OR GRAYLING BUTTERFLY. This large, curiously marked species is by no means uncommon on heaths and hilly places, where the caterpillar feeds most probably on grass, forming a cocoon in the earth, according to a French writer. This latter circumstance is very curious if true, and unique amongst British Butterflies; indeed there is only one Butterfly we have heard of, belonging to the genus *Zegris*, which makes a cocoon, although further researches may prove it to be not peculiar to

GRAYLING BUTTERFLY, UPPER AND UNDER SIDE.—(HIPPARCHIA SEVELE.)

one or two Butterflies. This species, as well as others of the genus, help to enliven the duller heaths; and the pedestrian, even though no entomologist, cannot fail to be struck with these brown butterflies and their more gay but smaller comrades, the *Blues* or *Polyommatus*. Our figure represents the upper and under sides of this species, and will show, better than any description, its markings and peculiarities.

THE HIPPARCHIA PAMPHILUS, OR GOLDEN EYE. This species of Butterfly, which makes its appearance in June, and again in September, on every grassy heath and common in the kingdom, has wings of a pale tawny above; the anterior with the margins dusky, and an ocellus near the tip; the posterior nearly resembling them, with an obsolete ocellus near the anal angle; beneath, the anterior wings are cinereous at the base and tip, with a rather large ocellus at the tip, white pupil, and whitish edge: the posterior wings are greenish-brown at the base, with an irregular pale band in the middle, in which are several minute indistinct ocelli; the margin greenish-brown. The body is deep fulvous; the antennæ tawny, with whitish annulations. The colour of the female is scarcely so deep as that

of the male, nor are the wings so distinctly edged with dusky above. The Caterpillar has a green hue, and is marked with white dorsal lines: it appears to prefer the dog's-tail grass to other food. Chrysalis green.

THE HIPPARCHIA HYPERANTHUS, OR RINGLET BUTTERFLY. Of this species of Butterfly there are many varieties, and some of them are scarce; for the most part, however, it is abundant in damp grassy woods and lanes, particularly in the north of Britain. The anterior wings above are plain brown, frequently with one or more black faintly ocellated spots; with three ocelli beneath towards the hinder margin: the posterior wings are also brown above, with two or more obsolete ocelli; beneath, with two approximating ocelli behind the middle of the anterior margin, and three parallel with the hinder margin: all the wings are paler beneath, and edged with a whitish fringe. The body is fuscous, paler beneath: the antennæ brown and lightly annulated. Caterpillar gray or dusky, with a black line behind; it subsists chiefly on the meadow grass, and resides at its roots: the chrysalis is bright brown, obscurely streaked.

THE HIPPARCHIA JANIRA, OR MEADOW BROWN BUTTERFLY. We know of none among the tribe of papilionaceous insects that is more common than this species; not a meadow or lane in Britain being scarcely to be seen in the month of July where it is wholly absent. The wings are of a dull dark brown or nearly black, the male usually having on the surface of the anterior pair near the tip a black ocellus with a white pupil; beneath fulvous, with the hinder margin grayish-brown; posterior wings beneath tawny-brown, with two or three dusky spots. Female generally with a large irregular tawny orange blotch on the anterior wings above, in which, as in the male, is an ocellus. In some specimens there is a deep black patch on the disc of the anterior wings; while in others irregular and undefined white blotches occur on various parts of the wings. The Caterpillar, which is green, with a white lateral line, and thickly covered with hair, feeds on meadow grass: the Chrysalis is yellowish-green, with dusky streaks on the head and wing-cases.

Knapp, speaking of it in his very interesting Journal of a Naturalist, where he describes the common occurrences of nature as observed near a village in the west of England, says, "Amid the tribes of insects particularly influenced by seasons, there are a few which appear little affected by common events; the brown meadow butterfly, so well known to every one, I have never missed in any year: and in those damp and cheerless summers when even the white cabbage butterfly is scarcely to be found, this creature may be seen in every transient gleam, drying its wings, and tripping from flower to flower with animation and life, nearly the sole possessor of the field and its sweets. Dry and exhausting as the summer may be, yet this dusky butterfly is uninjured by it, and we see it in profusion hovering about the sapless foliage."

The *HIPPARCHIA EGERIA*, or SPECKLED WOOD BUTTERFLY. This species seems to be pretty generally diffused throughout the United Kingdom; and several broods make their appearance between the beginning of April and the end of August. Anterior wings brown on both surfaces, with a number of yellowish spots, and an ocellus towards the tip; posterior wings above brown, with a series of yellowish spots, of which the three inner ones are ocellated, having a white

SPECKLED WOOD BUTTERFLY. UPPER AND UNDER SIDE. — (*HIPPARCHIA EGERIA*.)

pupill with a black iris, and surrounded by a yellowish circle; beneath they are brownish, with irregular angulated brown bands; the hinder margin purplish, with a series of white dots: the cilia are yellowish and brown: the body brown above, pale beneath; the antennæ brownish. The female is generally more spotted than the male, and the spots are larger. Caterpillar green, with white longitudinal lines; it feeds on couch grass. Chrysalis green, and short.

HIPPOCAMPUS. A genus of Lophobranchiate fish of a highly singular appearance, which has obtained the English name of the Sea-horse Pipe-fish. The best known species is the *Syngnathus Hippocampus* of Linnaeus, or *Hippocampus Brevicestris* of Cuvier. Its general length is from six to

SEA-HORSE — (*HIPPOCAMPUS BREVICESTRIS*)

ten inches; body much compressed, short, and deep; the whole length of the body and tail divided by longitudinal and transverse ridges, with tubercular points at the angles of intersection; snout slender; neck con-

tracting suddenly beyond the head; and the tail long, quadrangular, and terminating in a naked or finless tip. When swimming about, the *Hippocampus* maintains a vertical position; but the tail is ready to grasp whatever it meets in the water, and when fixed, the animal darts at its prey with great dexterity. In its dry or contracted state the fancied resemblance from which this fish takes its name is far more apparent than when alive. It is a native of the Mediterranean and Atlantic seas.

HIPPOLYTE. A genus of long-tailed Crustacea allied to the Shrimps, several species of which are found on our coasts. The British Museum contains these: descriptions and figures of them all are given in the works of Dr. Leach and of Prof. Bell on the British Crustacea.

HIPPONYX. A genus of Molluscous animals, of which there are numerous species, though until lately only known in a fossil state. The shell is obliquely cap-shaped; inequivalve, sub-equilateral, and destitute of ligament and hinge teeth; lower valve attached, sub-orbicular, with a muscular impression, composed of two lunulate portions, meeting at one extremity, and presenting the form of a horse-shoe; upper valve conical, with the apex inclined backwards, and the muscular impression marginal. These animals are generally supported on a solid shelly plate, but not always, the same object being gained when a suitable place of attachment can be found by their adhering to other shells.

HIPPOTAMUS, or RIVER-HORSE. This gigantic inhabitant of the African rivers is as formidable as the Rhinoceros, and in bulk inferior only to the Elephant, but its limbs are so short that its belly almost touches the ground. Its form is in the highest degree uncouth: the body being

HIPPOTAMUS. — (*H. AFRICANUS*.)

extremely bulky, fat, and round; the legs very short and clumsy; the head immensely large; the mouth prodigiously wide, and the teeth of vast strength and size, the incisors and canines of the lower jaw being long, and curved forwards: these canines, or tusks, sometimes measure more than two feet in length, and weigh upwards of six pounds each. Those in the upper jaw are much smaller; and the front teeth are of a moderate size. The lips are very thick and broad, and are beset, here and there, with scattered tufts of short bristles: the nostrils

are rather small, and open on the top of the muzzle: the eyes, which are very small, are situated high in the head: the ears are small, slightly pointed, and lined with short soft hair. The tail is short, thick, and sparingly covered with hair. The feet are

SKELETON OF THE HIPPOPOTAMUS.

large, and have four toes, terminated in separate hoofs. When just emerged from the water, the Hippopotamus appears of a pallid brown, or mouse-colour, with a bluish cast on the upper parts; and the belly is flesh-coloured, the skin appearing through the hair: but when perfectly dry, the animal's general colour is an obscure brown.

In the interior of Africa, where the rivers run through countries overshadowed by large forests, the Hippopotamus walks about at the bottom of the stream, raising its head at intervals above the surface, for the purpose of respiration. By night it quits its watery residence in search of its food, which consists of the herbage that grows near the banks of the rivers, and the surrounding pastures. It is not confined to rivers, however; for it also tenants the inland lakes, and is sometimes seen even in the sea, though it will not drink salt water, prey on fish, or live on any kind of animal food. Its voice is described as a peculiar kind of interrupted roar, between that of a bull and the braying of an elephant. When on land it moves in a somewhat slow and awkward manner, but if pursued, can run with considerable speed, and directly plunging into the water sinks to the bottom, and pursues its progress beneath. It is extremely cautious of making its appearance by day, in places much frequented by mankind; but is fearless in rivers which run through unfrequented regions; where it is occasionally seen to rush out of the water with sudden impetuosity, trampling down every thing in its way. At such times it is of course highly dangerous; and it sometimes also shows great fury when only slightly provoked: but it is naturally of a harmless disposition; not attacking other animals, but merely committing havoc in plantations of maize, rice, sugar-canes, &c., and destroying trees, by loosening the roots with its vast and powerful teeth.

The Hippopotamus sleeps in the small reedy islets which are here and there found in the rivers it frequents. In such spots it also brings forth its young; having only one at a birth, which it nurses with great care. These animals are occasionally shot, or harpooned; but they are said to be most successfully taken by pitfalls, prepared for them

near the rivers. But it is chiefly on account of the tusks and teeth that this animal is killed; their hardness being superior to that of ivory, while they are at the same time less liable to turn yellow. The skin, from its great thickness and strength, when dried, is formed into shields, and is said to be bullet-proof; the living animal, indeed, if shot at anywhere but on the head or belly, is scarcely vulnerable; nor is this wonderful when we consider that the hide is two inches deep or more on the back and sides. The flesh of this animal is eaten by the inhabitants of South Africa, and, as would appear from the reports of travellers, with more than usual gusto when it is in a half putrid state. The Hippopotamus has properly been considered as the Behemoth of Scripture. Most interesting accounts of the Hippopotamus have recently appeared in the works of Livingstone, Andersson, Cumming, and other African travellers, whilst visitors to the Zoological Gardens, Regent's Park, may now observe the habits of two very fine specimens, male and female. At the Parisian menagerie a similar pair have twice bred, but the young were in both instances destroyed by their mother.

HIPOPODUS. A genus of Conchifera, of which there is but one known recent species, the *Hippopus maculatus* (or Bear's-paw Clam) from the Indian Ocean. The delicate whiteness of the interior, the undulating edge, the radiated fluted columns, and the richness of the variegated colouring are such as to entitle it to the admiration of every one. It is equivalve, regular, and inequilateral; valves closed; transverse; ligament external; shell imbricated with numerous tubercles. It is not nearly so large as the *Tridacna*, but the animal is similar to it. [See *TRIDACNA*.]

HIRUDO. [See *LEECH*.]

HIRUNDO; HIRUNDINIDÆ. A genus and family of Fissirostral or wide-gaping birds of the Cuvierian system, embracing the Swallow tribe. Our British species are occasional visitors, and the heralds of summer; but at the approach of winter they resort chiefly, as is supposed, to Africa. [See *SWALLOW*.]

HIISPIDÆ. A family of Coleopterous insects popularly known in the United States as "little leaf-beetles." The upper side of these beetles is generally rough, as the generic name implies. The larvæ burrow under the skin of the leaves of plants, and eat the pulpy substance within, so that the skin, over and under the place of its operations, turns brown and dries, and has somewhat of a blistered appearance, and within these blistered spots the larvæ or grubs, the pupæ, or the beetles may often be found. The eggs of these insects are little rough blackish grains, and are glued to the upper side of the leaves, sometimes singly, and sometimes in clusters of four or five together. The grubs are about one-fifth of an inch in length, when fully grown. The body is oblong, flattened, rather broader before than behind, soft, and of a whitish colour, except

the head and the top of the first ring, which are brown, and of a horny consistence. The pupa state lasts only about a week, soon after which the beetles come out of their burrows.

The leaves of the apple-tree in North America are inhabited, according to Dr. Harris, by some of these little mining insects, which, in the beetle state, are probably the *Hispia rosea*, or rosy *Hispia*. They are of a deep tawny or reddish-yellow colour above, marked with little deep red lines and spots. The head is small, the antennæ are short, and of a black colour; the thorax is narrow before and wide behind, rough above, striped with deep red on each side; the wing-covers taken together form an oblong square; there are three smooth longitudinal lines or ribs on each of them, spotted with blood red, and the spaces between these lines are deeply punctured in double rows; the under side of the body is black, and the legs are short and reddish. They measure about one-fifth of an inch in length. These beetles may be found on the leaves of the apple-tree during the latter part of May and the beginning of June. A small species is found in this country (*H. testacea*).

HISTER: HISTERIDÆ; or MIMIC BEETLES. A genus and family of Coleoptera, which, from the power they possess of contracting their limbs and counterfeiting death, evidently derive their name from the Latin word *Histrion*, a stage mimic. The beetles belonging to this group are distinguished by the very hard consistence of the body, which is generally of an oblong-quadrate form, and of a highly polished surface. The antennæ are short, elbowed, and terminated by a large and solid club; the mandibles very robust, horny, and exerted; the maxillæ elongated and bifid; the labium bipartite and setose; the palpi filiform; the legs more or less dentate, the two posterior pairs being inserted widely apart; and the elytra generally short and truncate. These insects seldom exceed a third of an inch in length; their colours are generally black and shining; some few have the elytra ornamented with blood-coloured or pale buff spots, or exhibit metallic tints. They creep slowly, but fly well. They feed upon decaying vegetable and animal matter, and are

MIMIC BEETLE.—(HISTER QUADRINOTATUS.)

found very abundantly in the spring in the dung of horses and cows; some species, whose flattened bodies are admirably adapted to their mode of life, reside beneath the

bark of trees; while some of the more minute species are constantly found as residents in ants' nests. The larvæ are linear, depressed, nearly smooth, of a soft consistence, and white colour; and feed upon the same substance as the perfect insect.

HOBBY. (*Falco subbuteo*.) A bird of the long-winged Hawk kind, formerly used in the humbler walks of falconry, chiefly for larks and other small birds, which were caught in a singular manner: when the Hawk was cast off, the larks, keeping close to the ground through fear, became an easy prey to the fowler, who drew a net over them. The Hobby is about twelve inches in length; has a prominent and crooked bill; the orbits of the eyes are yellow, and over each eye is a light-coloured streak. The crown of the head, the back, and the coverts of the wings, are bluish black; the hinder part of the neck is marked with two pale yellow spots; and each cheek with a large black spot pointing downwards. The breast and belly are pale, marked with dusky streaks; wings brown; the two middle tail feathers deep dove colour, the others barred with rusty, and tipped with white; the legs and feet are yellow. The female is considerably larger than the male; the spots on her breast are more conspicuous; and her legs are greenish. She builds in high trees; and lays three or four bluish white eggs, irregularly spotted with grey and olive; but the Hobby is a bird of passage; and though it breeds here, it migrates from this country in October.

HOG. (*Sus*.) As all the varieties of this useful quadruped are derived from the Wild Boar, we shall proceed to describe that animal before we speak of the domestic species; merely premising that the genus *Sus* is in some points of an ambiguous nature, appearing to form at once a link between the cloven-footed, the whole-hoofed, and the digitated quadrupeds.

The Wild Boar is a native of almost all the temperate parts both of Europe and Asia. In times of yore it was not an unfrequent inhabitant of our own woods and forests; where it served as a beast of chase, as it still does to India, as well as in some parts of Continental Europe; presenting not only the most interesting and exciting sport to the hunters, but at the same time one of the most dangerous in which they can be engaged. This fierce and powerful animal is armed with long, curved, and sharp tusks, capable of inflicting the most severe and fatal wounds; but as he advances in age (after he has passed his fifth year), he becomes less dangerous, on account of the growth of these formidable tusks, which turn up so considerably as often to impede rather than assist his intentions of wounding with them. We learn from Buffon, that wild Boars follow their common parent until they have passed their third year, never wandering alone till they have acquired sufficient strength to resist the attacks of the wolf. "These animals," says he, "when they have young, form a kind of flock, and it is upon this alone that their safety depends. When at-

tacked, the largest and strongest front the enemy, and by pressing all round against the weaker, force them into the centre. Domestic Hogs are also observed to defend themselves in the same manner. The Wild Boar is hunted with dogs, or killed by surprise during the night, when the moon shines. As he flies slowly, leaves a strong odour behind him, and defends himself against the dogs, and often wounds them dangerously, fine hunting-dogs are unnecessary; and they would have their nose spoiled and acquire a habit of moving slowly by hunting him. Mastiffs, with very little training, are sufficient. The oldest Boars, which are known by the track of their feet, should alone be hunted: a young Boar of three years old is difficult to be attacked; because he runs very far without stopping; but the old Boars do not run far, allow the dogs to come near, and often stop to repel them. During the day the Boar commonly keeps in his soil, which is in the most sequestered part of the woods, and comes out by night in quest of food; and in summer, when the grain is ripe, it is easy to surprise him among the cultivated fields, which he frequents every night."

The Wild Boar is in general more ganut and bony, the muscular strength much greater, and the temper far more savage, than the domestic Hog. It is of a dark brindled gray colour, or blackish; but when only a year or two old, is of a dull yellowish brown cast; and when quite young, is marked by alternate dusky and pale longitudinal bands along the sides. Between the bristles, next the skin, is a finer or softer hair, of a woolly or curly nature. The snout is somewhat longer in proportion than that of the domestic species; but the principal difference is in the length of the tusks,

WILD BOAR—(SUS SCROFA.)

Though ordinarily timid and inoffensive, it is found that the females show the most determined courage when their young are attacked, and defend them with all imaginable fierceness. If two Boars chance to meet in the early part of the year, at which time the male seeks the female, the most furious encounters ensue. By a forest law of William I. (A. D. 1087), it was ordained that any who were found guilty of killing the Stag, the Roehuck, or the Wild Boar, should have their eyes put out!

The Common, or DOMESTIC HOG (*Sus scrofa*) differs from the wild animal princi-

pally in having smaller tusks and larger ears, which are also somewhat pendent and of a more pointed form. In colour, as well as size, it varies very considerably, but the prevailing cast is a dull yellowish white, marked or spotted irregularly with black, sometimes perfectly plain or unspotted, sometimes rufous, and sometimes totally black. Of all quadrupeds the Hog is the

BERKSHIRE HOG.

most gross in his manners, and has therefore been generally regarded as the very personification of impurity. The Jews were strictly enjoined not to eat its flesh; and the Mahometans agree in this respect with the Mosiac prohibition. In most parts of Europe, however, it constitutes a very material part of the food of mankind. And we may do well to reflect, while we deery the filthy habits of this animal, that from our own sensations we are often apt to form a partial judgment, and overlook that wise decree of Providence which adapts every part of creation to its respective inhabitants. The Hog is an animal of a remarkably prolific nature; and, as they bring forth from ten to fifteen, and sometimes twenty, at a litter, they would soon become very numerous, were they not diminished for the support of man. Their flesh, says Linnæus, is wholesome food for persons of athletic constitutions, or those who habituate themselves to much exercise, but improper for such as lead sedentary lives. It is, however, an article of general consumption, and one which is of great importance to a naval and commercial nation, as it takes salt better than any other flesh, and consequently is capable of being longer preserved.

The Jews and Mahometans not only abstain from the flesh of swine from a religious principle, but even consider themselves defiled by touching it. The Chinese, on the contrary, are so excessively fond of pork, that many, owing to this partiality alone, as it is said, have been prevented from conversion to Mahometanism. The fat of swine differs, in its situation, from that of almost every other quadruped, as it forms a thick, distinct, and continued layer betwixt the flesh and the skin. Lard, which is chiefly obtained from the fat membranes of the abdomen, is applicable to various uses, both culinary and medicinal; and when good, is white and moderately hard. The skin, when properly dressed, is used for the seats of saddles; it is also employed by various artificers.

Great attention has been paid in this country to the improvement of the various breeds; and by judicious crosses much has been effected both as to quality and size.

Some counties in the south-western division of England are considered famous for their breed of Hogs; those of Hampshire, Sussex, Wilts, and Berks being foremost; but since the pains that have of late years been taken by breeders of stock generally throughout the country, and the impetus given to their exertions by the various agricultural associations, we may fairly presume that all manifest the same praiseworthy solicitude in endeavouring to excel in this as in every other branch of rural economy. But this part of the subject, perhaps, does not properly fall within our province; for it has been said, that where art begins, the history of nature ought to end. We shall therefore not notice the different qualities which distinguish one breed from another, but conclude with Mr. Bell's remarks on a well-known variety of the Porcine genus—the Chinese Hog. "The introduction of the Chinese Hog has effected an astonishing change in the native breeds, wherever they have been crossed by it. This very remarkable variety deserves particular mention, not merely as a source of great improvement in an important branch of stock, but also as connected with a zoological question of great interest. M. Frederic Cuvier believed, that it is derived from a wild stock specifically distinct from the Wild Boar; and could this be proved, it would go far to settle the long disputed and difficult question of specific distinctions, as connected with the production of infertile progeny: for in that case, as the breed between the Chinese and the Common Hog is perfectly fertile, the argument for specific distinction founded upon that circumstance at once falls to the ground. On the other hand, however, those who contend that the production of fertile young is a proof of specific identity in the parents, would of course hold that the supposition of the celebrated naturalist is erroneous upon this very ground. The Chinese Hog is of small size, short and thick; the belly deep, and when fat, nearly reaching the ground; the legs short and fine; the head very short, and the neck thick. Its influence on the different breeds with which it has intermixed, has been greatly to improve them in the delicacy of the flesh; but while the pork of the Chinese cross is certainly excellent, some of our own breeds are still esteemed as yielding by far the best bacon and hams."

HOG, ETHIOPIAN. (*Phacochærus Æthiopicus*.) This animal is distinguished from the Common Hog by a pair of large, flat, semicircular lobes under the eyes; the snout is also much broader, and is very strong and callous; the ears are large, and slightly pointed; the tusks in the lower jaw are rather small, but those in the upper are large, sharp, and much curved; they have no fore-teeth, their place being supplied by very hard gums; immediately below the eyes the skin is loose and wrinkled, and on each side the corners of the mouth is a callous protuberance. The body is strong, and the limbs muscular; the tail is rather flat, and thinly covered with scattered hairs;

the colour of the whole animal, a dusky brown. It is a native of the hotter parts of Africa, residing principally in subterraneous recesses, which it digs with its nose and hoofs. When attacked or pursued, it rushes on its adversary like the Boar, and shows great fierceness.

HOG-LOUSE. [See ONTISCUS.]

HOLIBUT, or HALIBUT. (*Pleuronectes hippoglossus*.) This fish not only exceeds in size all the flounder genus, but ranks as one of the largest of fishes; sometimes attaining a length of six or seven feet, and a weight of 300 or 400 lbs. It is a native of the Northern and Mediterranean seas, and appears to arrive at its greatest size in the former. It is considered as the most voracious of its tribe; preying on a variety of other fishes and crustacea. The colour of the Holibut is deep brown above, and white beneath; the body being quite smooth, and the scales moderately small. Its flesh is coarse and dry, but it admits of being salted; and it constitutes no inconsiderable part of the food of the Greenlanders, who cut it into thin slices, and dry it in the sun. In the London markets this fish is usually cut into large pieces when exposed for sale.

HOLOTHURIADÆ. A family of Echinodermata, the distinguishing characters of which are, that the body is of an elongated form, defended by a coriaceous integument; open at both ends, and perforated by numerous small canals, through which suckers are protruded. At the anterior extremity is the mouth, furnished with many retractile tentacula, and at the opposite end is the aperture of the cloaca.

The *Holothurie* of the European seas are neither numerous nor brilliantly coloured; but in more tropical seas, where coral reefs rise within a moderate distance of the surface, as in the Red Sea, and the seas to the north and east of Australia, they are exceedingly numerous, and many of them splendidly coloured; so that, together with other Radiata of this and other orders, they make the sea-bottom, when seen by the light of an almost vertical sun, as gay as a tropical garden. The *Holothuria* resemble cucumbers; and various *Actinæ*, when their tentacula are expanded, have as gay an appearance as the flowers of almost any plants. Many of this species are esculent, and of a very gelatinous nature. When properly prepared, the Chinese are exceedingly fond of them as a principal ingredient

EATABLE TREPANG.—(*HOLOTHURIA EDOLIS*.)

in restorative soups. The Malays catch and dry them in great quantities for the Chinese markets, where they fetch a high price, and are called *Trepang*.

We learn from a paper by Mr. C. W. Peach, read before the Royal Polytechnic Institution of Cornwall, that a species of

Holothuria, called the "Nigger" or "Cotton Spinner" by the Cornish fishermen, is very common in deep water off the Deadman, and is held by them in great detestation, from its throwing out what they call "cotton," and from its slimy nature, and also because where the "Niggers" are numerous and get into the crab-pots, it is very rarely that either crabs or lobsters are caught. Their appearance, when closed up, very much resembles a small cucumber, the back being dark—almost black at times—and the under part light yellowish green, which, with the thorn-like appendages on the back, make the appearance more complete. On being handled, they stain the hand light green. The head is furnished with twenty tentacula, which surround the mouth; the opening is tolerably large, and can be much expanded; and it is amusing to watch the motions of the tentacula acting as feeders. If the tentacula are viewed from the upper part they are club-shaped on the top, this club being placed on a footstalk an inch in length, which is retractile, and is invariably of a lighter colour than the top. When seen from the under side, they appear like the umbels of the elder, and are beautifully branched and tipped much in the manner of the elder flowers. They can completely close in their tentacula, which they do on being disturbed; and they use them at times as organs of locomotion. Outside the tentacula is a border of spines like processes on a skin, which reaches a short way up the tentacula, and serves as a covering when these are withdrawn. These spines very much resemble the thorns of the brier; the back and sides are covered with similar ones, but not in rows. The under side is furnished with feelers in very great numbers: these feelers they stretch out to a great length, and attach themselves firmly by them; so much so, that in trying to detach them the feelers have been frequently left behind. Each feeler has a small round calcareous plate at the tip, which, under the microscope, shows that it is composed of innumerable plates, an object of great beauty; these plates effervesce with acid and so do the plates of the mouth and tips of the processes. When the softer parts of the feelers are cut transversely, they are composed of fine tubes, and when magnified have very much the appearance of some of the corals. The animal is covered with a dark slimy mucilaginous skin, which peels off freely; underneath this it is light gray, and has a reticulated appearance. They are of various sizes and lengths, often nearly a foot in length, and thick in proportion; they sometimes draw themselves almost into a ball, at others are much inflated in the centre. At times they lie motionless, but generally they are in motion. These animals are enveloped in a film so tenacious that it is a difficult matter to rub them to pieces in the water; on exposure to air they lose their tenacity and crumble to pieces. This species of *Holothuria* is extremely irritable, and on being touched or disturbed, throws out a bunch of white taper threads, about an inch in length and one-eighth in

thickness; these soon become attenuated, either by the agitation of the water or the coming into contact with something, and are drawn into very long threads of great tenacity; they stick to every thing they touch, and from these the animals are called "cotton spinners" by the fishermen. This small bunch is drawn into a large mass of threads, so small that the finest sewing-cotton is not equal to it, and is no doubt one of the means of defence provided for its preservation.

IIOMARUS. A genus of long-tailed Crustacea, containing the LOBSTER [which see].

HOMOPTERA. An order of insects, distinguished by their possessing two pairs of wings, usually composed of a firm membrane, and not covered by scales; and by having the anterior pair of the same substance throughout, and roof-like when folded. The mouth is adapted for suction, the tongue being channelled, and surrounded by lancet-like organs, with which the tissues of plants are pierced. All the insects of this group subsist on vegetable juices; and among them there are many which do an incredible amount of damage to the gardea crops. This order may be divided into three sections: in the first, *Trinera*, the tarsi have three joints; in the second, *Dinera*, they have two; and in the third, *Monomera*, they have but one joint.

HONEY-GUIDE. (*Cuculus Indicator*—Sparm.) The birds to which this name is given inhabit various parts of Africa, and are closely allied to the Cuckoo tribe, but differ from them in hatching their own eggs. They are celebrated for their earious habit of guiding the natives to the nests of wild bees, enticing them to the spot by flitting before them, and reiterating a peculiar cry. They have a solid, conical, and arched beak; small head; body long and straight; toes strong and short; and wings reaching to the middle of the tail. The feathers are short, hard, and pressed close to the body; and the skin is so thick and tough as to protect them effectually from the stings of bees, unless the enraged insects attack their eyes. The nest of this Honey-guide is composed of slender filaments of bark woven together in the form of a bottle, the neck and opening hanging downwards; and it is said to be constructed in the hollow of trees, which the bird climbs like a woodpecker. The general colour is an olive-green, brownish on the upper parts, and inclining to yellow beneath. One species is described as being about seven inches in length; and another as ten inches: they are called, respectively, the Little and Great Honey-guide (*Indicator minor* and *Indicator major*).

HONEY-SUCKER, and HONEY-EATER. (*Anthochaera* and *Melivora*.) The Honey-suckers are a family of Birds, closely allied to the Humming-birds (*Trochilidae*), and peculiar to New Holland and the neighbouring islands. The chief difference consists in their bill and legs being stronger, and their powers of flight less conspicuous. Besides the juices of flowers, and the insects

obtained with them, many of these birds feed on berries; and one species is said to pick holes in the bark of trees, and to extract insects from them by means of its long

AUSTRALIAN HONEY EATER.
(*MELIPHAGA AUSTRALIANA*.)

tongue, very much after the manner of the Woodpecker. The truly national work of Mr. Gould, "The Birds of Australia," contains figures and descriptions of many species. Our figure is derived from his work. (See ANTHOCHERA: *MELIPHAGA*.)

HOOKTIP [MOTH]. A name given by collectors to Moths of the genera *Drepana* and *Platypteryx*.

HOOPOE. (*Upupa*.) A genus of birds bearing a close relationship to certain forms of the *Corvidæ* or Crow family. The bill is used in the same manner, and for the same purposes, as in the Hornbills; namely, for seizing insects, &c., squeezing them to death, and throwing them with a jerk into the throat. The tongue is short, and destitute of the power of extension.

The COMMON or EUROPEAN HOOPOE (*Upupa epops*) is an elegant bird, inhabiting the warmer and temperate parts of the old Continent, and migrating occasionally to the British Islands. It is about the size of a thrush, but is easily distinguished from it by its head being ornamented with a handsome crest, composed of cinnamon-coloured feathers of unequal lengths, having a white bar and black tips, which it can expand and depress at pleasure. Its bill is also much longer and more slender, and its feet much shorter. The colour of the head, neck, and body is pale ferruginous, darkest on the back and shoulders; the wings and tail are black, the former crossed by five white bars, the latter crossed in the middle by a white crescent. The Hoopoe feeds on various grubs, worms, &c.; hence it follows the retreat of the Nile in Egypt, whose neighbouring plains swarm with insect life; and it also frequents ploughed lands and pasture grounds, like the crows. It is more abundant on the continent of Europe than in Britain; but its sojourn in temperate climates is but short,

its arrival from warmer regions being late in the year, and its departure early. This migration, however, is not universal, since it is observed that great numbers of these

HOOPOE. — (*UPUPA EPOPS*.)

birds are constantly found about the towns and villages of Egypt, becoming very familiar with man, and building their nests in the immediate vicinity of his habitations. The flight of the Hoopoe is rather slow and undulating; and it seldom perches on trees. The name of the bird seems to be derived from its continually uttering, in soft and rapid tones, a peculiar sound, resembling *hoop, hoop, hoop*.

HOPLOPTERUS. A genus of birds allied to the Plovers; so named from the bony spine or projection on the shoulder of the wing. There are several species, of which the longest known is the SPUR-WINGED PLOVER of Africa (*H. spinosus*).

HOPPING DICK. The local name given to a species of Thrush (*Merula leucogenys*), common in Jamaica, whose lively and familiar manners, as well as his sable plumage, and clear, rich, and mellow song, greatly resemble the English Blackbird. "The forests skirting the mountain are his favourite haunt. If he frequents the open slopes and crests of the hills, he glides from tree to tree, just above the surface of the grass. If he rises above the lower branches of the pimento, or into some of the loftier shrubs, it is to visit the *Tillandsias*, or parasitical wild pines, to drink from within the heart-leaves at those reservoirs of collected dews, which are the only resource of the birds in these high mountains. His dark sooty plumage, his brilliant orange bill, and his habit, when surprised or disturbed, of escaping by running or flying low, and sounding all the while his alarm scream till he gets away into the thicket, completely identify him with the European Blackbird." — Gosse.

HORIADÆ. This family of Coleopterous insects is of very small extent, but the species are comparatively large, handsomely coloured, and principally confined to tropical countries. The larva of one of the species (*Horia maculata*), an inhabitant of South America and the West Indies, is said

to destroy the larva of a species of wild carpenter bee (*Xylocopa teredo*), which smokes its cells and deposits its eggs in the trunks of

CISSITES TESTACEA.

trees. Our figure represents the *Cissites testacea*, from the East Indies. It is distinguished from *Iloria* by the head being narrower than the thorax, and the posterior femora much thickened.

HORNBILL. (*Buceros.*) This family of Conirostral birds is remarkable for the very large size of the beak, and for an extraordinary protuberance with which this is surmounted. They are both carnivorous and frugivorous, feeding not only on various berries, fruits, and other vegetable matter, but also on the smaller kinds of animals, as mice and small birds, as well as on insects and any putrid animal substance. Their large bills are of much less real than apparent strength, and they vary considerably in appearance during the different periods of their age, the upper process or excrescence not exhibiting its genuine form till the full growth of the bird. When cut across, it is found to consist of a very loose bony substance; its interior being traversed in every direction by osseous fibres, the interspaces being quite hollow: all the bones, indeed, of this remarkable bird being more permeated by air than in any other species. They inhabit the warm parts of Asia and Africa; and in their general habits they seem to bear a considerable resemblance to the Crows. The larger species are very difficult of approach; and they perch on the branches of high trees, where their vision can command an extensive range. They may be said to hold the same rank in the old continent that the Toucans do in America; not only from the enormous size of the bill, but also from their habit of swallowing their food whole, throwing it up into the air, and catching it as it falls. There are many species; but two will suffice for our description.

THE RHINOCEROS HORNBILL. (*Buceros Rhinoceros.*) This bird is about the size, though rather more slender, than a hen turkey; its colour black, except the lower part of the belly and tip of the tail, which are white: the bill is about ten inches in length, slightly curved, sharp-pointed, irregularly serrated on the edges, and furnished at the base of the upper mandible with an immense appendage in the form of a reverted

horn: a longitudinal black line divides this process, the part above it being of a bright red, the part below yellow, and the base of

RHINOCEROS HORNBILL.
(*BUCEROS RHINOCEROS.*)

it black; the bill itself is black at the base, tinged with bright red, and the remainder is yellow: the legs are short, strong, and of a pale yellow colour.

THE UNDULATED HORNBILL. (*Buceros undulatus.*) The beak of this species is more proportioned to the size of the bird, and the colours have more variety and elegance than in any other of the tribe. The length of the bill is about thirty inches, exclusive of the bill, which is only five. The plumage is black, with a strong gloss of blue, and a large patch of red-brown between the shoulders: the chin, the orbits of the eyes, and the space between them and the upper mandible, are covered by a bluish bare skin; the bill is a pale yellow, tinged with brown; and is moderately curved and sharp-pointed.

HORNED OWL. [See OWL.]

HORNET. (*Vespa crabro.*) This insect is of the Wasp kind, but much more formidable, and very considerably larger. It has four wings, the first pair being by far the largest, and with these it flies with great velocity. The head is oblong, and yellowish; the eyes are prominent and semilunate; and between them there are two falseform antennae. The body is united to the shoulders by a slender filament; the middle of the fore part is of a dark brown hue, marked with a deep yellow belt; and the hinder part is wholly of that colour, except that it is variegated with eight brown spots. The Hornet, like the Wasp, is extremely voracious, and preys on almost any kind of fresh animal substances which it can obtain, as well as on honey, fruit, &c. Its sting is greatly to be dreaded, and is often productive of very serious consequences. The Hornet's nest is generally built in the cavity of some decayed tree, or immediately beneath its roots; and not unfrequently in timber yards and other similar situations. It is of a smaller size than that of the Wasp, and of a somewhat globular form, with the mouths

of the cells downwards, which in a great measure preserves them from the rain. In "The Zoologist," p. 162. F. Smith, Esq., Curator of the Entomological Society, thus writes:—"A few years ago, as I was walking by the side of Virginia Water, by moonlight, I heard a loud booming noise, evidently caused by some insect darting rapidly by. I was for some time at a loss to conceive what this could be; at last I succeeded in knocking one down, when I found it was a hornet. By watching the flight of others, I soon discovered the tree containing their nest: they were carrying on their labours by the light of the moon, apparently quite as busily as if it had been open day." [See VESPERINA.]

This brief notice of the Hornet leads us to extract from the "Journal of a Naturalist" some interesting remarks relative to this insect:—"Every-day events manifest to very superficial observation, that no created being, from the monster of the ocean, 'that makes the deep boil like a pot of ointment,' to the insect that feebly creeps on the ground, exists free from the persecutions or annoyance of another. Some may be subject to fewer injuries than others, but none are wholly exempt: the strong assail by power, and become assaulted themselves by the minute or weak. This year (1826) the Hornet abounded with us in unusual numbers, and afforded constant evidence of its power and voracity that could not have been exceeded by any ravenous beast. In our gardens the inglorious murmur of four or five of them at a time might be frequently heard about our fruit-trees. They would occasionally extract the sweet liquor from the gage, or other rich plums; but the prime object of their visit was to seize the wasps that frequented the same places. This they not only did when the creature was feeding on the fruit, but would hawk after them when on the wing; capture them with a facility to which their heavy flight seemed unequal; bear them to some neighbouring plant, and there feed on the insect, which seemed perfectly overpowered by the might of the Hornet. The first operation was to snip off the head, then to cut away the lower part by the waist; and, when near, we could hear them shearing away the outer coat from the body, and crushing it with their strong mandibles; sometimes devouring it, but generally only sucking the juices it contained. Their avidity for this sort of food is very manifest, when the grape ripens on the wall: being commonly the only remaining fruit, the wasp abounds there; the Hornets flock to the prey, and we may see them in constant progress, bearing their victims from the bunches. The wasp itself seizes the house-fly; but this seems rather the display of wanton power than for food, as it bears the fly about with it for a length of time, and drops it unconsumed. The fly, in its turn, is conducive, after its manner, to the death of many an animal. We know not any insect that destroys the Hornet; but its power and being are terminated by some very effective agent, as in particular years it is almost unknown." To the foregoing the

author appends the following note:—"The Hornet is a very pugnacious animal. They will fight desperately with each other at times, when they meet in pursuit of prey, biting each other's body, and trying to get their mandibles under the head of their opponent, to snip it off. I one day confined, under a glass, two of these creatures which had been fighting. One had evidently the mastery; but both had been so injured in the contest, that they soon died; and it is most probable that they fall victims to each other's voracity in the cold damp season that usually terminates the autumn of our year."

HORNET (SPHINX). A name given by collectors to Hawk-moths of the genus *Trochilium*.

HORSE. (*Equus caballus*.) This most useful and beautiful quadruped demands, perhaps, a more extended notice than the ordinary limits of this work may seem to afford; but we trust we have not omitted any material point, zoological or historical, that is essential to a complete description of an animal, whose services to mankind are everywhere deemed invaluable, and whose noble nature universally excites man's admiration. It has been well observed, that had not custom diminished the Lion with the title of "king of beasts," reason could nowhere confer that honour more deservedly than on the Horse. His courage, strength, fleetness, his symmetrical form, and grandeur of deportment, are unalloyed by any quality injurious to other creatures, or calculated to create the aversion of man; whose orders he implicitly obeys, whose severest tasks he undertakes with a cheerful alacrity, and whose pleasures he contributes to with animation and delight. Nor is this all: for, when called to bear our warriors to the battlefield, nothing can excel his resolute fierceness, his courageous ardour! In the poetical language of the Sacred Writings, "His neck is clothed with thunder. The glory of his nostrils is terrible. He paweth the valley, and rejoiceth in his strength. He goeth on to meet the armed men. He knocketh at danger, and is not affrighted; neither turneth he back from the sword." (Job, xxxix.)

What region the Horse originally inhabited, or to what nation we are indebted for his first subjugation, are questions far too remote for history to resolve. That this animal is of Eastern origin, and that the Egyptians were the first to reduce it to obedience, and train it to the various purposes of civilized life, appears highly probable from various passages in the Bible, though no direct testimony of such a fact is to be gathered from that source. The first mention of the Horse occurs during the wise administration of Joseph in Egypt, who, we are told, gave the famishing inhabitants bread "in exchange for horses;" and also when the body of the patriarch Jacob was removed from Egypt to Canaan for burial, we read that "there went up with him both chariots and horsemen." The period when the Horse is thus indicated as a beast both of draught and burden, is 1650 years before the

birth of Christ; which is a date anterior to any that profane history affords on the subject.

The generic characteristics of the Horse are a broad undivided hoof; six cutting-teeth or *nippers* in each jaw; two very small tusks or canines; grinders with a flat crown, presenting, when worn, different figures, formed by the enamelled plates of the interior; stomach small and simple, intestines very large. Wild Horses exist in many countries; but Arabia produces the most beautiful breed, and also the most generous, swift, courageous, and persevering. They occur, though not in great numbers, even in the deserts of that country, and the natives make use of every stratagem to take them. They select the most promising for breeding, and, instead of crossing the breed, the utmost care is taken to keep it entire. In other countries it is found necessary to change the races, otherwise, it is said, the Horses would soon degenerate; but in Arabia the same blood has passed down through a long succession, without any diminution either of beauty or strength. A general relief has hence arisen, and been long maintained, that to Arabia are we indebted for the primitive breed of this noble animal, and for its subjugation to man's use. This opinion, however, has been combated by Mr. Bell (in his History of British Quadrupeds) in the following terms: "The long acknowledged superiority of the Horses of Arabia is no proof that they were indigenous to that arid country in a wild state; for there is great reason to conclude that it was only at a comparatively late period that they were employed by that people. Whilst Solomon was receiving from Arabia treasures of various kinds, it was from Egypt only that his Horses were brought: and so highly were they valued by this magnificent and luxurious king, that notwithstanding the Divine prohibition, 'that the king shall not multiply Horses to himself, nor cause his people to return into Egypt, to the end that he should multiply Horses,' it is stated that he had no less than forty thousand stalls of Horses for his chariots, and twelve thousand horsemen. There appears great probability, therefore, in the opinion that Egypt or its neighbourhood is its original country; and still more, that this extraordinary people first rendered it subservient to man, and subsequently distributed it to other countries."

It does not appear, then, that a clue can be obtained to determine, with any degree of precision, in what country the Horse first roamed at large, or where he first submitted to the yoke of man. Those which at present exist in a wild state seem to have been derived from such as had been once domesticated. In the Pampas or plains of South America, on the banks of the river La Plata, there are immense troops of wild horses, which are descended from those of Andalusia, originally carried thither by the Spanish conquerors: and we learn from the accounts given by various travellers, that they not only associate together in herds or troops of several thousands, but that on the

appearance of any danger, they evidently put themselves under the direction of a leader, in order the more effectually to resist the enemy's attack. Large herds are sometimes seen in the southern parts of Siberia, in the deserts of the Mongul territory, and among the Kalhas to the north-west of China. Moldavia also abounds with them. At the Cape of Good Hope there are numbers of wild Horses, but they are small and vicious. They are likewise found in other parts of Africa, but the savages there seem ignorant of their value, and also of the methods of taming them.

In Brande's Dictionary of Science, &c. it is remarked, that "wild Horses appear to be free from nearly all those diseases to which the domestic breed are prone. They are generally of a pale or grayish-brown colour, with brown mane and tail, a whitish muzzle changing to black about the mouth. They are less than the domestic breed; with a larger head; longer legs; larger ears, with the apices sub-reflected; the forehead is more convex above the eyes; the hoofs are contracted and sub-cylindrical; mane sub-erect, less lax than in the domestic horse; the coat, in winter, looser and sub-undulated along the back; the tail not very large. They recognize the presence of man at a great distance when he approaches them to windward, and fly from him with wonderful speed; they prefer sunny slopes, and avoid forests and steep places. They do not wander beyond the fiftieth degree of north latitude. Wild stallions attracted by domestic mares are often taken and killed. The first change which domestication works upon the form of the wild Horse is to increase the bulk of his trunk as compared with his head and limbs. This change is beautifully exemplified in the Arabian, which we must regard as an early, if not first remove from his wild neighbours of the more northern deserts, and which the Bedouin still hunts for the sake of their flesh. The head is not only proportionally smaller, but is remarkable for the breadth and squareness of the forehead, the shortness and fineness of the muzzle, the prominence and brilliancy of the eye, and the smallness of the ears. The body is still somewhat light, and narrow at the fore part; but the shoulder is superior in its formation to that in any other breed. The Arabian seldom stands more than fourteen hands two inches. The 'Barb,' so called from its native country, Barbary, is somewhat smaller than its nearly the Arabian; it seldom exceeds fourteen hands and an inch; the shoulders are flat, the chest round, the legs rather long, and the head small and very beautiful. The Barb is remarkable for its fine and graceful action; but though it is superior to the Arabian in its general form, it has not its untiring spirit or its speed. Our most valuable English varieties of the Horse date from the introduction of, and interbreeding with, the Barb and Arabian."

The Horse is naturally an herbivorous animal, and is more scrupulous in the choice of his food than most other domestic quadrupeds; in the meadow rejecting several

plants which the ox devours with pleasure. His thin and muscular lips, his firm and compressed mouth, and his sharp incisor teeth, are admirably adapted to seize and to crop the grass; and when, free from man's control, he can follow his own propensities, we all know that grass is his chosen food: yet, in order that he may subsist (as in his present state of domestication he necessarily must) on aliment of a much harder kind, he is enabled, by the peculiar structure of some of the bones of his face, so to move his jaws as to comminute and grind down his "corn."—Of the various modes of judging of a Horse's age, the best is from a careful inspection of the teeth. Five days after birth, the four teeth in front, called *nickers*, begin to shoot; these are cast off at the age of two years and a half, but are soon renewed; and in the following year two above and two below, namely one on each side of the *nickers*, are also thrown off; at four years and a half other four next those last placed fall out, and are succeeded by other four, which grow much more slowly. From these last four corner teeth it is that the animal's age is distinguished, for they are somewhat hollowed in the middle, and have a black mark in the cavities. At five years old these teeth scarcely rise above the gums; at six, their hollow pits begin to fill up, and turn to a brown spot; and before eight years the mark generally disappears. A Horse's age is also indicated by the canine teeth or tusks, for those in the under jaw generally shoot at three years and a half, and the two in the upper at four; till six they continue sharp at the points; but at ten they appear long and blunted. There are, however, many circumstances which render a decision as to the age of the Horse very difficult after the marks are effaced from the lower incisors; and it should be observed, that Horses which are always kept in the stable have the mark much sooner worn out than those that are at grass; to say nothing of the various artful tricks resorted to by dealers and jockeys to deceive the inexperienced and unwary.

The Horse has three natural paces, namely, walking, trotting, and galloping. In the first, he moves off with one of his fore feet, which is immediately followed by the hind leg of the opposite side; and so with the other fore and hind leg. His trot differs from his walk, not only in its greater velocity, but also in this, that he always moves the two opposite legs together. The gallop is a series of leaps, and it is true and regular, when the horse lifts his two feet on one side at the same time, and follows with those on the other side. These three natural paces may be converted into artificial paces by art and skill. But as this is a part of the science of horsemanship, it is not necessary to be more than adverted to in this place: we shall therefore merely observe, that the trot is the pace which enables all quadrupeds to balance and support themselves with ease and firmness; and it is therefore the most proper for ensuring a free determined motion to the Horse.

An old writer, Camerarius, says, a perfect

Horse should have the breast broad, the hips round, and the mane long, the countenance fierce like a lion, a nose like a sheep, the head, legs, and skin of a deer, the throat and neck of a wolf, and the ear and tail of a fox. This is as graphic as it is concise; but to be serviceable it is much too general: we therefore turn to the pages of the Penny Cyclopædia for fuller particulars as to the proper conformation of the Horse. "The head should not be disproportionally large, and should be well set on; i. e. the lower jaw-bones should be sufficiently far apart to enable the head to form that angle with the neck which gives free motion and a graceful carriage to it, and prevents its bearing too heavy on the hand. The eye should be large and a little prominent, and the eyelid fine and thin. The ear should be small and erect, and quick in motion. The top-car indicates dulness or stubbornness; and when it is habitually laid too far back upon the neck, there is too frequently a disposition to mischief. The nostril in every breed should be somewhat expanded: it can hardly be too much so in the Racer, the Hunter, the Roadster, and the Coach-horse, for this animal breathes only through the nostril, and would be dangerously distressed when much speed is required of him, if the nostril could not dilate to admit and to return the air. The neck should be long rather than short. It then enables the animal to graze with more ease, and to throw his weight more forward, whether he is in harness or galloping at the top of his speed. It should be muscular at its base, and gradually become fine as it approaches the head. The withers should be somewhat high in every Horse, except perhaps that of heavy draught, and it does not harm him, for there is larger surface for the attachment of the muscles of the back, and they act at greater mechanical advantage. A slanting direction of the shoulder gives also much mechanical advantage, as well as an easy and pleasant action, and a greater degree of safety. It must not however exist in any considerable degree in the Horse of draught, and particularly of heavy draught. The chest must be capacious, for it contains the heart and the lungs, the organs on which the speed and endurance of the Horse depend. Capacity of chest is indispensable in every Horse, but the form of the chest admits of variation. In the wagon-horse the circular chest may be admitted, because he seldom goes at any great speed, and there is comparatively little variation in the quantity of air required; but in other Horses the variation is often fearful. The quantity of air expended in the gallop is many times that required in hard work. Here we must have depth of chest, not only as giving more room for the insertion of the muscles on the action of which the expansion of the chest depends, but a conformation of the chest which admits of that expansion. That which is somewhat straight may be easily bent into a circle when greater capacity is required; that which is already circular admits of no expansion. A few words more are all that our limits permit us to add, and they contain almost all that is necessary on the conformation of

the Horse. The loins should be broad, the quarters long, the thighs muscular, and the hocks well bent and well under the Horse."

Some peculiarity of breed distinguishes the Horses of most civilized countries; or, rather, there is some particular breed for which one country is more celebrated than others. Thus there is the Spanish Genette, a small but fleet and beautiful variety, which is generally ranked next to the Barb: their heads are rather large, their manes thick, their ears long and well pointed, their shoulders somewhat heavy, their chests full and large, and their legs clean and handsome. They move with great ease, and carry themselves very gracefully. They are usually of a black or dark bay colour; and some of them, particularly such as come from the province of Andalusia, are said to possess, in a superior degree, high courage, docility, and other estimable qualities.—France produces a motley breed; adapted rather for the purposes of war than of the chase, and generally considered as heavy-shouldered. But great attention has of late years been paid to the improvement of them by crosses with the best bred English varieties; a remark, by the by, which may in a great measure be applied to the breed of Horses elsewhere throughout the continent. And we may safely assert, that whatever could be gained from long experience and careful assiduity, whatever wealth could procure, or skill effect, in order to arrive at perfection in the various breeds, and in the proper training, of this noble animal, has been fully attained in England.

It is impossible to say at what early period the Horse was first considered an object of interest in Britain; but we know that when our rude and warlike ancestors had to contend with the Rooman invaders, they depended much on their cavalry and war-chariots, which they managed with great skill and dexterity. We likewise know that the Saxons paid great attention to the Horse, and took considerable pains to improve the natural breed. King Athelstan obtained several German running-horses from Hugh Capet of France; and William the Conqueror, with his Norman followers, introduced the Spanish horse, in whose veins ran the blood of the swift-footed Barb. When the Crusaders returned from the Holy Land, they brought with them many a noble Eastern steed; and from that time a greater admixture of Arabian blood with the Horses of Europe was a natural consequence. It must however be apparent, when we remember with what a heavy load of armour both horseman and horse were encumbered, that our mail-clad warriors must necessarily have required horses of prodigious strength, and that fleetness was of far less consequence to them than weight and mettle. King John, who appears to have devoted much attention to the breed of Horses, imported a hundred choice stallions of the Flanders kind; to which act may probably be traced the foundation of that character for size, strength, and vigour, which English horses, whether for draught or war, have since maintained. Subsequent monarchs also evinced a strong

desire for keeping up, undiminished, a race of Horses which, in a national point of view, had become so valuable, and their exportation was accordingly forbidden. At the period to which we have been alluding, the breeds of Horses most in repute for superior weight and strength were those of Flanders and Normandy. In course of time, the cumbersome armour, the battle-axe and shield, were laid aside; and when the sword and carbine, with the lighter dresses of our cavalry, were introduced, speed and elegance were deemed of more account than size and power. At length the sports of the field engaged the attention and became the amusement of kings and princes; the nobility of the land vied with each other in keeping the choicest studs, the English Hunter was unmatched for ardour in the chase, combined with the most persevering endurance; and the English Race-horse distanced all competition.

RACE-HORSE.

The RACE-HORSE. "Whether or not the blood of our finest Racers be pure Eastern, or a mixture of the Arabian or Barb with the best of our English stock," Mr. Bell observes, "can scarcely, with all the accuracy of our turf genealogy, be positively ascertained: but it is undoubted that the most celebrated Horses that this country has ever produced are traceable from son to sire back to some or other of the well-known Arabian, Barbary, or Turkish stallions which have at different times been imported. The importance of the influence of the sire in breeding Horses is in no point more clearly proved than by the fact that the progeny of the most celebrated Horses have generally sustained the reputation of their sires. Thus the descendants of Eclipse numbered no less than three hundred and sixty-four winners." "The Racer is generally distinguished by his beautiful Arabian head; his fine and finely-set-on neck; his oblique lengthened shoulders; well-bent hinder legs, his ample muscular quarters; his flat legs, rather short from the knee downwards; and his long elastic pastern. From this perfect symmetry, however, many celebrated Race-horses have shown remarkable deviations; and yet they have not failed to enter into the excitation and enjoyment of the sport, straining every muscle, and evincing indescribable

energy in their endeavours to outstrip their competitors.

The HUNTER. It is generally allowed that this fine animal, whose spirit is only equalled by his endurance of fatigue, and whose speed is on a par with his beautiful form, presents a happy combination of those

THE HUNTER

qualities which give swiftness to the racer, vigour to the charger, and muscular power to the draught-horse. "The first property of a good hunter is, that he should be light in hand. For this purpose his head must be small; his neck thin, especially beneath; his crest firm and arched; and his jaws wide. The head will then be well set on. It will form a pleasant angle with the neck, which gives a light and pleasant mouth."

The compact and serviceable ROAD-STER, "a hunter in miniature," as a perfect specimen of this truly valuable animal has been called; the splendid CARRIAGE HORSE, with

COACH-HORSE.

his arched crest and high action; the powerful DRAY HORSE, whose united strength and size (derived from the Suffolk Punch and the Flanders breed) are unequalled; the round-chested and long-backed SUFFOLK PUNCH HORSE; and the patient CART HORSE,—have each their peculiar merits, and require careful attention to the breed and management. We have also some smaller varieties, excellent in their kind: as the useful GALLOWAY; the diminutive and hardy SHELTON PONY; and the sturdy, rough Pony bred in the New Forest. But our limits have long warned us to bring this article to a close: we therefore beg to refer our readers to the various works which are exclusively devoted to "the Horse" for whatever further information may be required;

and conclude by briefly remarking, that according to the degree of cultivation bestowed on them, Horses improve or degenerate; their qualities of sagacity and docility alone remaining inherent.

CART-HORSE.

A curious point, and one of great interest in the investigation of zoological relations, which may be properly introduced in this place, is—"that the characters of the male parent of the mother's first progeny show themselves in her subsequent offspring by other males, however different those males may be in form and colour. Mr. Bell observes that this truth has been illustrated by him when treating on the Dog and on the Hog, and he adds that it receives a remarkable and interesting confirmation from the case of a mare belonging to the Earl of Morton, to which he had before alluded. In that case the mare was young, and after producing the female hybrid by the Quagga, had first a filly, and afterwards a colt, by a fine black Arabian Horse. They both resembled the Quagga in the dark line along the back, the stripes across the forehead, and the bars across the legs: in the filly the mane was short and stiff, like that of the Quagga; in the colt it was long, but so stiff as to arch upwards and hang clear of the sides of the neck; in other respects they were nearly pure Arabian. This and other such cases should not be forgotten by breeders of animals, who are anxious about the perfection of their stock, and should make them particularly careful as to the male influence which first makes its impression on the female.

The mode of catching and taming wild horses in South America is so well described by Mr. Darwin, in his "Researches," and shows so strikingly what mastery over the brute creation man can attain, that we trust it will be considered an appropriate addendum to the foregoing. "A troop of wild young horses is driven into the corral, or large enclosure of stakes, and the door is shut. We will suppose that one man alone has to catch and mount a horse, which as yet had never felt bridle or saddle. I conceive, except by a Gaucho, such a feat would be utterly impracticable. The Gaucho picks out a full-grown colt; and as the beast rushes round the circus, he throws his lasso so as to catch both the front legs. Instantly the horse rolls over with a heavy shock, and,

whilst struggling on the ground, the Gauchó, holding the lazo tight, makes a circle, so as to catch one of the hind legs, just beneath the fetlock, and draws it close to the two front. He then hitches the lazo, so that the three legs are bound together. Then sitting on the horse's neck, he fixes a strong bridle, without a bit, to the lower jaw. This he does by passing a narrow thong through the eye-holes, at the end of the reins, and several times round both jaw and tongue. The two front legs are now tied closely together, with a strong leathern thong, fastened by a slip-knot. The lazo, which bound the three together, being then loosed, the horse rises with difficulty. The Gauchó now holding fast the bridle fixed to the lower jaw, leads the horse outside the corral. If a second man is present (otherwise the trouble is much greater) he holds the animal's head, whilst the first puts on the horsecloths and saddle, and girths the whole together. During this operation, the horse, from dread and astonishment at thus being bound round the waist, throws himself, over and over again, on the ground, and, till beaten, is unwilling to rise. At last, when the saddling is finished, the poor animal can hardly breathe from fear, and is white with foam and sweat. The man now prepares to mount, by pressing heavily on the stirrup, so that the horse may not lose its balance; and at the moment he throws his leg over the animal's back he pulls the slip-knot, and the beast is free. Some "domidors" (horse-smbdners) pull the knot while the animal is lying on the ground, and, standing over the saddle, allow it to rise beneath them. The horse, wild with dread, gives a few most violent bounds, and then starts off at full gallop: when quite exhausted, the man, by patience, brings him back to the corral, where, reeking hot, and scarcely alive, the poor beast is let free. Those animals which will not gallop away, but obstinately throw themselves on the ground, are by far the most troublesome. This process is tremendously severe, but in two or three trials the horse is tamed. It is not, however, for some weeks that the animal is ridden with the iron bit and solid ring; for it must learn to associate the will of its rider with the feel of the rein, before the most powerful bridle can be of any service."

HORSE-GUARD. This name, we are informed by Mr Douchéday, is applied in the United States to Hymenopterous insects of the genus *Monedula*, from their habit of capturing Gadflies (*Tabani*).

HOUND. There are several species of Dogs which come under this appellation, as the Foxhound, Greyhound, Bloodhound, &c. which will be found in their proper alphabetical order in this volume. Hounds may be distinguished into such as discover and pursue the game by sight; and those which find and pursue it by the excellence of their scent.

HOUND-FISH. The name applied sometimes to different species of the Shark family. [See DOG-FISH.]

HOWLET. (*Strix aluco*.) A bird of the Owl kind, so called from its mournful, howling voice. It measures eighteen inches in length: the head, back, wings, and tail, are cinereous, with black and white spots; the head is large, round, and full-fledged; and the wings reach to the extremity of the tail.

HUMBLE-BEE. (*Bombus*.) Of the villose or hairy bees popularly called Humble-bees, there are several species. One of the largest and most common is the *Apis lapidarius* of Linnaeus, so named from the circumstance of its nest being generally situated in stony or gravelly places. This species is entirely of a deep black colour, except the end of the abdomen, which is red or orange-coloured, more or less deep in different individuals. The female is of large size, measuring nearly an inch in length: the male is considerably smaller, and the labouring bee is still smaller than the male.

Humble-bees are the only tribe besides the hive-bees that in this part of the world construct nests by the united labour of the society. Their habitations are sometimes excavated at a considerable depth in the ground, and sometimes built upon its surface, beneath stones, &c. The societies consist, in some species, of about fifty or sixty individuals; in others of as many as two or three hundred. They contain males, females, and workers or neuters. The females alone survive the winter; and they employ the first fine days in spring to commence their nests, which they very quickly excavate, and supply with a mixture of honey and pollen for the nourishment of the first brood, which consists exclusively of workers. These, after having undergone their transformations, assist in the construction of new cells, the collection of the food, and the rearing of the larvae. In autumn the males and females are produced; and at the commencement of winter all but the larger females die; these remain in a sort of chamber distinct from the rest, but, as it would appear, without any supply of food. It should be observed that though the Humble-bees collect honey as well as the common ones, it is neither so fine nor so good: nor is their wax so clean, or so capable of fusion.

HUMBLE-BEE FLY. (*Bombylius*.) A name very usually given to a species of the large order Diptera, comprehending species of different sizes, but all agreeing in the great resemblance they bear, at first sight, to the Humble-bees of the smaller or middle-sized kinds: but on examination, it will appear that they are destitute of trunks, and have but one pair of wings. Nature has assigned for the larvae of some of the species a very singular habitation—the intestines of horses, or under the thick skins of oxen. In the latter case, the worm hatched from the egg of its parent fly, deposited there, forms a tumour which furnishes it with food and lodging, and in the middle there is an aperture for the purpose of respiration. Some, however, feed on vegetable substances, and one species in particular shows a strong predilection for the bulbous roots of flowers.

HUMMING-BIRD. (*Trochilus*.) The birds included in the family of *Trochilidae*, or Humming-birds, are at once the most diminutive and the most brilliantly coloured of the whole feathered race. Their vivacity, swiftness, and singular appearance, unite in rendering them the admiration of mankind; while their colours are so radiant that we can only compare their peculiar splendour with the brilliancy of polished metals and the superior lustre of the ruby, the sapphire, or the emerald. This is their general character; but there are some species whose plumage is comparatively obscure, exhibiting only a golden-green tinge, diffused over the brow or purplish colour of the back and wings. In size they vary from that of a wren to a humble-bee; the muscles of their wings are very strong, and their plumage dense and compact; they are almost ever in motion; and the velocity with which they dart through the air, and the rapidly-vibrating motion of their wings, are quite inconceivable. These lovely gems of animated nature are peculiar to America, and almost exclusively tropical; some species, however, migrate into the temperate regions on either side of the equator during the warm season; and stragglers have occasionally been met with even in cold situations. They are characterized by a long and extremely slender bill, inclosing an extensible and retractile tongue, which is divided into two filaments from the middle to the tip, by which they extract the nectar and the small insects which may lurk in the recesses of flowers. Their feet are very small, their wings long and narrow; the mechanism of their whole form being, in fact, like that of the Swift, formed for rapid and powerful flight. When hovering before a flower, they seem suspended in the air, rather than sustained by the vigorous movement of their pinions; and it is to the constant murmur or buzzing sound, caused by the rapid vibration of them, that these beautiful little creatures derive their name. How greatly they must add to the richness of a Transatlantic landscape, when fluttering from flower to flower in the morning sunbeams!

"Wherever a creeping vine opens its fragrant clusters, or wherever a tree-flower blooms, may these little things be seen. In the garden or in the woods, over the water, every where they are darting about; of all sizes, from one that might easily be mistaken for a different variety of bird, to the tiny Hermit (*T. ruficoster*), whose body is not half the size of the bees buzzing about the same sweets. Sometimes they are seen chasing each other in sport with a rapidity of flight and intricacy of path the eye is puzzled to follow. Again circling round and round, they rise high in mid air, then dart off like light to some distant attraction. Perched upon a little limb, they smooth their plumes and seem to delight in their dazzling hues; then starting off leisurely, they skim along, stopping capriciously to kiss the coquetting flowerets. Often two meet in mid air and furiously fight, their crests and the feathers upon their throats all erected and blazing, and altogether pictures of the most

violent rage. Several times we saw them battling with large black bees, who frequent the same flowers, and may be supposed often to interfere provokingly. Like lightning our little heroes would come down, but the coat of shining mail would ward their furious strokes. Again and again would they renew the attack, until their anger had expended itself by its own fury, or until the apothetic bee, once roused, had put forth powers that drove the invader from the field."—*Edwards's Voyage up the Amazon.*

The Humming-birds are generally divided into two classes—those with curved bills, and those whose bills are straight. We shall endeavour to give a description of the most remarkable species; reserving some of them for insertion under the article *Trochilidae*. Their nests are very beautifully constructed, being usually composed of vegetable down, such as that of the cotton-plant or silk-cotton tree; and being covered on the outside with bits of lichen, leaves, moss, &c. Sometimes they are suspended from the extremities of twigs of the orange, the pomegranate, or the citron-tree; and sometimes from a house, provided they can find convenient twigs for the purpose; for it is to be observed, that although these birds are most numerous in the dense forests, where the wild blossoms almost vie with themselves in splendour, they are also seen in the gardens of cultivated districts, and do not appear at all disinclined to the society of Man, though it is very difficult to keep them in a state of domestication. The Humming-bird is very irascible, two males scarcely ever meeting without a contest ensuing; they will also attack birds of a much larger size, as wrens or king-birds, and they sometimes even have contests for a flower with the humble-bee.

TOPAZ-THROATED HUMMING-BIRD. (*Trochilus pella*.) Both in size and colour this species is decidedly superior to any others of the curve-billed kind. Its body is as large as that of a wren; and from the tip of the bill to the end of the two long-tailed feathers, it measures from eight to ten inches. The upper part of the head and neck are of a glossy black, the back and smaller wing-coverts being of a fine deep orange-purple colour; the throat and part of the neck of the most splendid topaz yellow, changing from the lustre of polished gold to deep emerald green, according to the situations in which it is viewed: the topaz-coloured plumage is separated from the breast and sides of the neck by a black line, beneath which the whole breast and sides are of a deep but shining purple rose-colour: the wings are of a purplish brown; the rump of a bright grass-green; and the tail orange-purple, except the two middle feathers, which are purple-brown, of a narrow shape, and pointed at the tips, and exceed the rest in length by about four inches. The bill is moderately long, curved, and black; the legs are also black. The female is far less brilliant than the male, being of a dark coppery-green colour, with dusky wings, and

the two middle feathers of the tail no longer than the rest. This species is said to be principally found in Surinam and Guiana, where it frequents the banks of rivers and brooks, the surface of which they skim after the manner of swallows.

FORK-TAILED HUMMING-BIRD. (*Trochilus forficatus*.) This species is chiefly noticeable for the shining beauty of its tail-feathers, which appear of a brilliant blue, green, or golden colour, according to the lights in which they are seen, and form a very long and broad tail in proportion to the body of the bird: the crown of the head is blue, and a shining golden lustre pervades the rest of the plumage, but it is trifling in comparison with the beauty of the tail: the legs, feet, and claws are black.

BAR-TAILED HUMMING-BIRD. (*Trochilus sparganius*.) This elegant bird is nearly eight inches long: its colour is green-gold, but not very bright, except on the throat, where it is rich and brilliant: the tail is long and strongly forked, and the feathers are velvet-black, each being crossed by a broad golden crimson bar, and rounded at the end: bill and legs black. Native of Peru.

HALEQUIN HUMMING-BIRD. (*Trochilus multicolor*.) A highly elegant species, remarkable for the variety of its colours. Its length is about four inches: the bill long, slightly bent, and of a pale yellow hue: the crown of the head, throat, neck, breast, upper part of the back, rump, and wing-coverts, fine gilded grass-green: the whole upper part of the neck, ultramarine blue, divided from the green of the back by a narrow black bar: the wings and tail light brown; belly and vent-feathers red; wings long in proportion to the bird; tail rounded at the tip.

CRESTED HUMMING-BIRD. (*Trochilus cristatus*.) This bird is a native of the West Indies: the bill is slender, sharp-pointed, incurved, and blackish; the top of the head, from the bill to the hinder part, which terminates in a crest, is partly green and partly blue, and shines with a most brilliant metallic lustre: the plumage on the upper part of the body and wings is dark green intermixed with gold colour; the breast and belly are of a dingy grey; the tail is a bluish-black, glossy on the upper surface; and the legs and feet, which are very small, are blackish.

SAPPHIRE AND EMERALD HUMMING-BIRD. (*Trochilus bicolor*.) The two brilliant colours with which this bird is invested, not only merit the title of the gems by which they are called, but possess a vivid metallic splendour not exhibited by the gems themselves. The sapphire colour covers the head and throat, beyond which it blends with the lucid golden emerald colour of the breast, belly, and back: the wings are brown; the tail glossy bluish-black; and the belly white: the upper mandible is black, the lower whitish. Native of South America and the West Indies.

RUBY-THROATED HUMMING-BIRD. (*Trochilus colubris*.) This beautiful species is about three inches and a half in length from the tip of the bill to that of the tail: the bill is black; the crown, upper part of the neck, back, and coverts of the wings are of a most resplendent and variable green and gold colour; the chin and throat rival the ruby in brilliancy, changing, according to the light, either into a burnished gold colour, or a deep brown tint: the breast and belly are white; the wings and tail purplish-brown, but the two middle tail-feathers green. It is a native of, and continues in the southern parts of the American continent during the whole year, but appears in North America only in summer. It breeds in Florida, Carolina, and some of the West India islands; and is even seen in Canada. In that entertaining book, "The Canadian Naturalist," this bird and its habits are thus noticed in one of the "Conversations:—" "C. Had there is what I have long wished to see, a humming-bird sucking the flowers. There are two of them: let us take a closer view of them.—F. No, no: stay where you are, and remain quite still, and talk in a low voice: for on the slightest alarm, and their brilliant little eyes are glancing in every direction, they shoot off with the straightness and speed of an arrow. See how they hover on the wing, in front of the blossoms, quite

N. AMERICAN HUMMING-BIRD.
(*TROCHILUS COLUBRIS*.)

stationary, while their long tongue is inserted, but their wings vibrating so rapidly as to be only visible as an indistinct cloud on each side.—C. One of them has suddenly vanished, but I did not see him fly, though I was watching him.—F. He has gone only about a yard: you may see him stationary again to the right of where he was before. These starts are so sudden and so rapid, that they are often lost to the sight.—C. How very little and how very beautiful! the body glitters in the sun with green and gold, and the throat is just like a glowing coal of fire. Now they rest on a twig; one of them I perceive has not the brilliant throat of the other.—F. That is the female; in other respects her plumage is like that of the male. It is the Ruby-throated Humming-bird (*Trochilus colubris*), and is scattered

over the whole of this continent, at least to the latitude of 57 degrees north."

LEAST HUMMING-BIRD. (*Trochilus minimus*.) This is the smallest of the whole feathered tribe; being about an inch and a quarter in length, and weighing only about twenty grains: the general colour on the upper parts is green gold; the quill and tail feathers glossy violet-brown, and the exterior tail-feathers edged and tipped with white; the under parts of the body are of a dull white; and the legs and feet black. Native of several parts of South America, and of some of the West India islands.

The **LONG-TAILED HUMMING-BIRD** (*Trochilus polytmus*) is called by Mr. Gosse "the gem of American ornithology;" its slender form, velvet crest, emerald bosom, and lengthened tail-plumes, rendering it one of the most elegant even of this most brilliant family. The length of the male is ten inches and a quarter; wings expanded, six and three-eighths, and longest tail-feather seven inches and a half. Irides black; beak coral red, the tip black; feet purplish-brown, soles paler. Crown, hind head, and nape deep

LONG-TAILED HUMMING-BIRD: MALE.
(*TROCHILUS POLYTMUS*.)

velvety-black, very slightly glossed; back, rump, wing, and tail-coverts, rich golden green; wings purplish-black; tail deep black, with bluish gloss, the uropygials, and

the outer edges of the others, glossed with golden green, varying in intensity. The tail is slightly forked, the feathers regularly graduating from the uropygials outwards, save that the outmost but one is exceedingly lengthened. Throat, breast, and belly, gorgeous emerald-green, extending to the thighs; vent and under tail-coverts, purplish black. The plumage of the hind head long and loose, descending in two lateral tufts upon the nape, which are to some extent erectile. The whole upper plumage of the female, from the hind head, is rich golden green; tail blue black, the exterior two feathers on each side broadly tipped with white; uropygials golden-green. Wings as in the male. Under parts white, the feathers having round tips of metallic green on the sides of the neck, and being mingled with green ones on the sides of the body.

"The Long-tail is a permanent resident in Jamaica, and is not uncommonly seen at all seasons and in all situations. It loves to frequent the margins of woods and roadsides, where it sucks the blossoms of the trees, occasionally descending, however, to the low shrubs. There is one locality where it is abundant, the summit of that range of mountains just behind Bluefields, and known as the Bluefields Ridge. Behind the peaks which are visible from the sea, at an elevation of about half a mile, there runs through the dense woods a narrow path, just passable for a horse, overrun with beautiful ferns of many graceful forms, and always damp and cool. No habitation occurs within several miles, and no cultivation, save the isolated provision grounds of the negroes, which are teeming with enormous arums, and these are hidden from view far up in the thick woods. The refreshing coolness of this road, its unbroken solitude, combined with the peculiarity and luxuriance of the vegetation, made it one of my favourite resorts. Not a tree, from the thickness of one's wrist up to the giant magnitude of the hoary figs and cotton trees, but is clothed with fantastic parasites; begonias with waxen flowers, and ferns with hirsute stems, climb up the trunks; enormous bromelias spring from the greater forks, and fringe the horizontal limbs; various orchideæ with matted roots and grotesque blossoms droop from every bough, and long lianes, like the cordage of a ship, depend from the loftiest branches, or stretch from tree to tree. Elegant tree-ferns and towering palms are numerous; here and there the wild plantain or heliconia waves its long flag-like leaves from amidst the humbler bushes, and in the most obscure corners over some decaying log, nods the noble spike of a magnificent limodorum. Nothing is flaunting or showy; all is solemn and subdued; but all is exquisitely beautiful. Now and then the ear is startled by the long-drawn measured notes, most richly sweet, of the Solitaire, itself mysteriously unseen, like the hymn of praise of an angel. It is so in keeping with the solitude, and with the scene, that we are unconsciously arrested to admire and listen. The smaller wood consists largely of the plant called Glass-eye berry, a Scrophula-

rious shrub, the blossoms of which, though presenting little beauty in form or hue, are pre-eminently attractive to the Long-tailed Humming-bird. These bushes are at no part of the year out of blossom, the scarlet berries appearing at all seasons on the same stalk as the flowers. And here at any time one may with tolerable certainty calculate on finding these very lovely birds. But it is in March, April, and May that they abound: I suppose I have sometimes seen not fewer than a hundred come successively to rife the blossoms within the space of half as many yards in the course of a forenoon. They are, however, in no respect gregarious; though three or four may be at one moment hovering round the blossoms of the same bush, there is no association; each is governed by his individual preference, and each attends to his own affairs."

"The Humming-birds in Jamaica do not confine themselves to any particular season for nidification. In almost every month of the year I have either found, or had brought to me, the nests of *Polytmus* in occupation. Still, as far as my experience goes, they are most numerous in June; while Mr. Hill considers January as the most normal period. It is not improbable that two broods are reared in a season. In the latter part of February, a friend showed me a nest of this species in a singular situation, but which I afterwards found to be quite in accordance with its usual habits: it was composed wholly of moss, and suspended to one of the fibres, not thicker than whipcord, belonging to the root of a tree, and contained two eggs. Mr. Gosse goes on describing, in his peculiarly pleasant manner, his further operations in endeavouring to become acquainted with every particular respecting the nidification and general habits of this interesting species. We select one example. "On the 12th of November, we took, in Bluefields morass, the nest of a *Polytmus*, containing two eggs, one of which had the chick considerably advanced, the other was freshly laid. The nest was placed on a hanging twig of a black-mangrove tree, the twig passing perpendicularly through the side, and out at the bottom. It is now before me. It is a very compact cup, one inch and three quarters deep without, and one inch deep within; the sides about a quarter of an inch thick, the inner margin a little over-arching, so as to narrow the opening: the total diameter at top, one inch and a half; one inch in the clear. It is mainly composed of silk cotton very closely pressed, mixed with the still more glossy cotton of an *asclepias*, particularly round the edge; the seed remaining attached to some of the filaments. On the outside the whole structure is quite covered with spider's web, crossed and recrossed in every direction, and made to adhere by some viscons substance, evidently applied after the web was placed, probably saliva. Little bits of pale green lichen, and fragments of thin laminated bark, are stuck here and there on the outside, by means of the webs having been passed over them. The eggs are long-oval, pure white, save that, when fresh, the contents

produce a reddish tinge, from the thinness of the shell."

FEMALE LONG-TAILED HUMMING-BIRD.
AND NEST.

"All the Humming-birds have more or less the habit when in flight of pausing in the air, and throwing the body and tail into rapid and odd contortions; this seems to be most the case with *Mango*, but perhaps is more observable in *Polytmus* from the effect that such motions have on the beautiful long feathers of the tail. That the object of these quick turns is the capture of insects I am sure, having watched one thus engaged pretty close to me; I drew up and observed it carefully, and distinctly saw the minute flies in the air, which it pursued and caught, and heard repeatedly the snapping of the beak. My presence scarcely disturbed it, if at all. * * * When I left England, I had laid myself out for the attempt to bring these radiant creatures alive to this country: and after a little acquaintance with the Jamaican species, *Polytmus* seemed, from its beauty, its abundance, its size, its docility, and its mountain habitat, to be the species at once most likely to succeed, and most worthy of the effort. My expectations were disappointed: yet as the efforts themselves made me more familiar with their habits, the reader, I trust, will pardon some prolixity of detail in the narration of these attempts."

[We have already so fully availed ourselves of Mr. Gosse's labours, that we beg to refer, for further information, to the work itself; and we take the opportunity of assuring him, at the same time, that his readers will be far more inclined to applaud than to condemn what he is pleased to call his "prolixity." We have personally derived both pleasure and instruction from its perusal; and we trust that many who consult our volume will be induced, from the extracts they have seen, to become possessed of "The Birds of Jamaica;" for a more delightful specimen of descriptive ornithology never

came from the pen of a naturalist, thoroughly imbued with his subject, and perfectly competent to impart his knowledge to the world in the most enticing form.] The works of M. Bourcier and Mr. Gould on Humming-birds are full of figures of these living jewels. In 1851, the visitors to the Zoological Gardens were charmed with Mr. Gould's display of so many gorgeous groups of these birds.

HURON. (*Perca nigricans*.) An Acanthopterygian fish belonging to the family *Percidae*, known to the English settlers on the borders of Lake Huron by the name of "Black Bass"—the word *bass* being almost synonymous with *perch*. It haunts deep holes at the mouths of rivers or edges of banks, and readily takes a hook baited with a small fish, or a piece of white rag trailed after a boat, as in fishing for mackerel. The flesh is firm, white, and well-flavoured; and it is, accordingly, in high estimation as an article of food.

HYÆNA. A well-known genus of digitigrade and carnivorous quadrupeds, distinguished by having no tuberculous teeth or small teeth behind the carnivorous, while, from their peculiar conformation, aided by the enormous strength of their jaws, are adapted for crushing the hardest substances. The skull of the Hyæna is short, and re-

SKULL OF HYÆNA.

markable for its solidity; the muzzle also is short; and the temporal muscles, which raise the lower jaw, together with those of the neck, are very fully developed. The tongue is rough, the eyes are projecting, and the ears are large. The neck, chest, and shoulders are extremely powerful; but the hind-quarters are low, and the hind-legs seem comparatively feeble. It has four toes on each foot, furnished with blunt, stout, un retractile claws. Beneath the tail is a glandulous pouch, analogous to that of the Civets, but not secreting a similar odorous substance.

The common or **STRIPED HYÆNA** (*Hyæna vulgaris*) is a native of Asiatic Turkey, Syria, Abyssinia, &c. It is of a brownish gray colour, marked by several transverse dark brown bands on the body, which are more numerous as well as of a deeper colour on the legs: from the neck along the upper part of the back runs a strong bristly mane; the nose is black; the ears are rather long, sharp-pointed, and nearly naked; the tail is short rather than long, and very full of

hair. Many absurd notions respecting the Hyæna were entertained by the ancients—its annual change of sex, its imitation of the human voice, its power of charming or fascinating shepherds, &c., subjects which at

STRIPED HYÆNA.—(*HYÆNA VULGARIS*.)

the present day scarcely deserve to be mentioned. Hyænas generally inhabit caverns and rocky places, prowling about at night to feed on the remains of dead animals, or whatever living prey they can seize; but they seldom attack man, except in self-defence. As carrion-feeders they seem destined to fill up an important station in the economy of nature, by cleansing the earth of the decaying carcases of the larger beasts, whose remains might otherwise infect the atmosphere with pestilential effluvia. Though not gregarious from any social principle, they sometimes assemble in troops, and follow the movements of an army in order to feast on the bodies of those who perish on the field of battle: nay, it is asserted—nor is it inconsistent with their insatiable voracity and the peculiar strength of their claws—that they have been often known to tear newly-buried corpses out of their graves.

The aspect of the Hyæna seems to indicate a gloominess and malignity of disposition, with which its manners in a state of captivity appear in general to correspond: savageness and intractability mark its every look and movement; and it is said that its courage is equal to its rapacity. It was formerly supposed, and universally believed, that the Hyæna was untamable; but that it is possible, however difficult it may be, to tame it, there now exists not the shadow of a doubt. A remarkable peculiarity in this animal is, that when he is first obliged to run, he always appears lame for a considerable distance, and that, in some cases, to such a degree as to induce a belief that one of his legs is broken; but after running for some time, this halting disappears, and he proceeds on his course very swiftly. Mr. Bruce, the persevering and entertaining Abyssinian traveller, says, "I do not think there is any one that has hitherto written of this animal who ever saw the thousandth part of them that I have. They were a plague in Abyssinia in every situation, both in the city and in the field, and, I think, surpassed the sheep in number. Gondar was full of them from the time it turned dark till the dawn of day, seeking the different pieces of slaughtered carcases which this cruel and unclean people expose in the streets without burial, and who firmly believe that these animals are Falasha from the neighbouring mountains, transformed by magic,

and come down to eat human flesh in the dark in safety." "One night in Mait-ha, being very intent on observation, I heard something pass behind me towards the bed, but upon looking round could perceive nothing. Having finished what I was then about, I went out of my tent, intending directly to return, which I immediately did, when I perceived large blue eyes glaring at me in the dark. I called upon my servant with a light, and there was the Hyæna standing nigh the head of the bed, with two or three large bunches of candles in his mouth. To have fired at him I was in danger of breaking my quadrant or other furniture, and he seemed, by keeping the candles steadily in his mouth, to wish for no other prey at that time. As his mouth was full, and he had no claws to tear with, I was not afraid of him, but with a pike struck him as near the heart as I could judge. It was not till then he showed any sign of fierceness; but, upon feeling his wound, he let drop the candles, and endeavoured to run up the shaft of the spear to arrive at me, so that, in self-defence, I was obliged to draw a pistol from my girdle and shoot him, and nearly at the same time my servant cleft his skull with a battle-axe. In a word, the Hyæna was the plague of our lives, the terror of our night-walks, the destruction of our mules and asses, which above all others are his favourite food."

The SPOTTED HYÆNA bears a considerable resemblance to the former species, but is marked with numerous round blackish-brown spots instead of stripes, and the mane is much less. Its habits are similar to the Striped Hyæna, and it commits equal ravages

SPOTTED HYÆNA.—(HYÆNA CROCUTA.)

amongst the cattle of the districts in which it resides. This species inhabits many parts of Africa, but is numerous round the Cape of Good Hope, where it is much dreaded. It rarely, however, moves abroad during the day, but passes that period in a state of repose, either in holes in the ground, or in retired situations densely covered with bush. Till lately, it seems, Hyænas were in the habit of paying nightly visits to the streets of Cape Town, and were regarded as very useful in carrying away the animal refuse; but partly from better regulations now existing in the town, and partly from the number of these animals having greatly decreased, this no longer occurs. In the interior of Southern Africa the ravages of this beast

are still frightful, and it is no uncommon thing to find that they have entered the hut of a native in the night, and devoured or dreadfully mangled some of the younger branches of the family. And yet, notwithstanding this ferocity, the Spotted Hyæna is sometimes domiciliated in the houses of the peasantry, among whom, we are told, "he is preferred to the dog himself for attachment to his master, for general sagacity, and even, it is said, for his qualifications for the chase."

Another species (*Hyæna villosa*) is mentioned by Cuvier, as differing from the preceding by having stripes on the legs, the rest of the body being of a dark grayish-brown. It inhabits the south of Africa, and is known there under the name of the sea-shore wolf.

HYÆNA-DOG. A name given to the Wild Dog of the settlers at the Cape. It is smaller and more slender than either the Hyæna or the Wolf. In its general osteological structure it agrees with the dogs, and it has no mane; but the head resembles the Hyæna's, and it has only four toes to each foot. Its colour is a reddish-brown, with patches of black and white intermixed: nose and muzzle black, with a strong black line passing from them up the centre of the forehead to between the ears. It is fierce, swift, and active; is very destructive to animals which are less fleet and powerful than itself; and commits great havoc on sheep. It is the *Hyæna venatica* of Dr. Burchell's "Travels," and the *Lycaon* of Mr. Gray.

HYÆNODON. [See SUPPLEMENT.]

HYALÆA. A genus of *Pteropoda*, distinguished by their wing-shaped organs of locomotion. They are found in the Atlantic and Mediterranean, and the shell is known in this country by the trivial name

HYALÆA GLOBULOSA.

of Venus' Chariot. It is globose, glassy, and transparent, with a triangular opening at the upper part where the dorsal portion advances beyond the ventral, which is vaulted; dorsal more flat; lower extremity tridentate. The head of the animal is very indistinct, and it has no eyes.

HYALONEMA. A genus of siliceous sponges, by some considered a true zoophyte.

HYDATIDS. A term applied to nearly all kinds of cyst-like productions or cystic parasites invading the bodies of men and animals. They are now known to be only the young of higher forms of Entozoa.

HYDRA. The name given to a genus of minute polypi found in stagnant pools of

water, where numbers are often seen clustering upon aquatic plants, &c. These animals present us with the simplest kind of structure which has yet been ascertained. The Hydra consists simply of a fleshy tube, open at both extremities, and the aperture of the tube serving as a mouth, which is situate in the more dilated end, and this mouth is provided at its margin with a single row of *tentacula*, or long flexible arms, which diverge from each other like the spokes of a wheel. Looking to this animal, we may suppose that nature has formed it to prove that animal life may be carried

HYDRA FUSCA

on without the aid of the complicated machinery which she has given to the higher orders of creation. The *Hydra viridis*, or Green Polype, has the power of fixing itself in an erect position by the foot, and if it wishes to change place, it slowly bends till its head touches the plane on which it is moving, and adheres to it by the mouth, or one or two of its tentacles; the foot is then detached, and by a curve of the body placed close to the head, where it is again fixed, preparatory to a new step, which it performs by a repetition of the same movements. When in search of prey, the Hydra permits its arms to float loosely through the water; by which means it succeeds in obtaining a supply of food; for if, in their active course, any of the minute crustacea and aquatic worms should but touch one of the tentacula, it is immediately seized, other arms are soon coiled round it, and the unfortunate victim is speedily conveyed to the mouth.

With regard to the powers of reproduction possessed by these simple animals, it is to be observed that, when mature and well supplied with food, minute gemmules or buds are seen to become developed from the common substance of the body: these gemmules appear at first like delicate gelatinous tubercles upon the exterior of the parent polype; but, as they increase in size, they gradually assume a similar form, and become perforated at their unattached extremity. During the first period of the formation of these sprouts, they are evidently

continuous with the general substance from which they arise; but, at length, when the young is fully formed and ripe for independent existence, the point of union between the two becomes more and more slender, until a slight effort on the part of either is sufficient to detach them, and the process is completed.

But among the many remarkable features in the history of the Hydra, that which appears the most so, is its capability of reproducing the whole structure from separate portions of it. New tentacula will replace any which have been accidentally lost or removed. If the body is divided transversely, each segment will become a new animal; the upper one closing the aperture at its base, and the lower one speedily developing tentacula around the newly-formed mouth. If divided longitudinally, each half will, in a very short space of time, begin to ply its tentacula; nay, if cut transversely into several segments, each will in time become a perfect animal.—Trembley was the first man who gave a detailed account of this curious polype. [See POLYPE.]

HYDRACHNA. A genus of aquatic insects closely allied to the *Acarida* [which see]. One of the largest and by far the most elegant of the genus is the *Hydrachna geographicalis*, so named from the fancied map-like distribution of its variegations. Its shape is globular, and its colour a polished black, ornamented with red spots, which in a certain light have a kind of gilded lustre. The legs of this insect, as in the rest of the genus, are hairy; it swims with great celerity, and appears in almost constant motion. The eggs of the Hydrachna are small and round: the young, when first excluded, are furnished with six legs only; but they acquire two more legs after the first or second change of their skin.

HYDROBRANCHIATA. The first section of the order *Gastropoda*, containing Mollusca which breathe water only.

HYDROCANTHARI, or WATER BEETLES. The name of a great group of Coleoptera, containing *Dytiscus*, *Colymbetes*, and numerous other genera.

HYDROCHERUS. [See CAPTARA.]

HYDROMETRIDÆ. A family of insects, some species of which may be met with in almost every pool or stream, skimming along the surface, and turning about with the greatest rapidity. The body is boat-shaped, the hind feet serving as a rudder, while the two middle feet brush along the surface of the water, and give the required motion: the under side of the body is clothed with a thick coating of fine hairs, evidently intended to prevent the insect from coming in contact with the water.

HYDROPHILUS. A remarkable genus of aquatic insects, differing from that of *Dytiscus* only in the structure of the antennæ, which, instead of being setaceous, are short, and furnished with a clavated and perforated tip or knob. One large species, common in our ponds and ditches, is an inch

and a half long, oval, and of a deep brown colour, highly polished. The eggs are laid in a sort of cocoon, spun by the female, and coated with a gummy matter that is impervious to the water on which it floats. The larvæ are observed to prey on the smaller kinds of water-snails, tadpoles, &c., and appear very voracious; and they remain about two years before they change into pupæ or chrysalides. When the larva is arrived at

HYDROPHILUS FISCHER.

its full growth, it secretes itself in the bank of the water it inhabits, and having formed a convenient cell, lies dormant for some time; after which it divests itself of its skin, and appears in the form of a chrysalis; in this state it remains some time longer, when it again releases itself of its exuvie, appears in its complete or beetle form, and as soon as the elytra or wing-cases acquire a sufficient degree of strength and colour; it comes forth from its retreat, and commits itself in its new form to its native element. It is a curious circumstance that some of the species of *Hydrophilidae* found in this country exceed in size those from tropical climates; many of the species are, however, very minute. [See *DRYINUS*.]

HYDROPHIS, or WATER-SNAKE.

This genus of reptiles is very common in certain parts of the Indian Seas, where it feeds on fishes, and is considered excessively venomous. They have the back part of the body and tail very much compressed and

WATER SNAKE.—(HYDROPHIS.)

raised vertically, which, imparting to them the power of swimming, renders them aquatic animals. They have a range of scales a little broader than the rest under the belly; the head small, not bulged, obtuse, and covered with large plates. Several species are found in the salt water of Bengal, and others in the Indian Ocean.

HYDRUS. A species of small aquatic serpents, having the extremity of their tails enlarged, and very much compressed; which conformation gives them greater facility in moving through the water. They inhabit the Intertropical parts of Asia, and the neighbouring islands, and in some situations are very abundant.

HYLA. A genus of Batrachian reptiles, known as *Tree Frogs*, and generically differing from the common Frogs in no respect, excepting that the extremity of each of their toes is widened and rounded into a sort of viscous palette, which enables them to adhere to the surfaces of bodies, and to climb trees, to which last they resort during the summer, in pursuit of insects; but they deposit their eggs in water, and penetrate into the mud in winter, like other Frogs.

The *TREE FROG* (*Hyla arborea*) exceeds all other European species in the beauty of its colours; the elegance of its form, and the agility of its movements; while its size is smaller than any of the tribe. It is a native of France, Germany, Italy, and many other countries of Europe, but is not found in the British islands. During the summer months its principal residence is on the upper parts of trees, where it wanders among the foliage in quest of insects, which it catches with extreme celerity, either stealing softly towards its prey, or springing upon it with a sudden leap; and it is often seen suspending itself by its feet to the under parts of the leaves, to enjoy their shade. Its colour on the upper parts is green, more or less bright; the abdomen is whitish, and marked by numerous granules: on each side of the body is a dark violet-coloured streak, tinged underneath with yellow, separating the green of the upper parts from the white colour of the lower. The body is short, plump, and smooth: the hind legs are very long and slender; the fore feet have four and the hind feet five toes, all of which are terminated by round, flat, and dilated tips, the under surface of which, being soft and glutinous, enables the animal to hang with perfect security from the leaves of trees, &c.; it can also adhere to any substance by its abdomen, which is covered with small glandular granules, by merely pressing itself against it. Though the Tree Frog inhabits the woods during the summer months, yet on the approach of winter it retires to the waters, and there submerging itself in the soft mud, or concealing itself beneath the banks, remains in a state of torpidity, and again emerges in the spring, at which period it deposits its spawn in the water, like the rest, in small clustered masses. The male at this period inflates its throat in a surprising manner, and croaks in so loud and

sharp a key as to be heard at an immense distance. During their residence among the trees they are observed to be particularly noisy on the approach of rain.

HYLÆOSAURUS. [See SUPPLEMENT.]

HYLOBATES. [See APE, Long-armed.]

HYMENOPTERA. An order of insects having four naked membranous wings, as seen in Bees, Wasps, Ants, Ichneumons, &c. The anterior wings are usually much larger than the posterior; and the nervures or hard framework on which the membrane of the wing is extended are but few. The mouth is furnished with mandibles and maxillæ, and the abdomen is terminated either by an ovipositor or a sting. The larvæ of some resemble those of the order Lepidoptera, but differ in the number of their legs, &c. Most hymenopterous insects, when in the perfect state, are constantly resorting to flowers, either for the purpose of gathering honey, or of preying upon the less powerful species of their own class. Hymenopterous insects love the light of the sun; they take wing only during the day-time, remaining at rest in the night, and in dull and wet weather; and it must be admitted that they excel all other insects in the number and variety of their instincts, which are wonderfully displayed in the methods employed by them in providing not merely for their own welfare, but for the comfort and future wants of their offspring.

In the adult state these insects live chiefly on the honey and pollen of flowers, and the juices of fruits. The larvæ of the Saw-flies (*Tenthredinidae*), under the form of false caterpillars and slugs, are leaf-eaters, and are oftentimes productive of much injury to plants. The larvæ of the *Xiphydriade*, and of the Horn-tails (*Uroceridae*), are borers and wood-eaters, and consequently injurious to the plants inhabited by them. Pines and firs suffer most from their attacks. Some of the warty excrescences on the leaves and stems of plants, such as oak-apples, gall-nuts, and the like, arise from the punctures of four-winged gall-flies (*Diptolepididae*), and the irritation produced by their larvæ, which reside in these swellings. The injury caused by them is, comparatively, of very little importance, while, on the other hand, we are greatly indebted to these insects for the gall-nuts that are extensively used in colouring, and in medicine, and form the chief ingredient in ink. We may, therefore, write down these insects among the benefactors of the human race. Immense numbers of caterpillars and other noxious insects are preyed upon by internal enemies, the larvæ of the ichneumon-flies (*Evaniidae*, *Ichneumonidae*, and *Chalcididae*), which live upon the fat of their victims, and finally destroy them. Some of these ichneumon-flies (*Ichneumonæ ovulorum*) are extremely small, and confine their attacks to the eggs of other insects, which they puncture, and the little creatures, reduced from the latter find a sufficient quantity of food to supply all their wants within the larger eggs they occupy. The ruby-tails (*Chrysididae*), and the cuckoo-

bees (*Hylæus*, *Sphecodes*, *Nomada*, *Melecta*, *Epeolus*, *Cœliorhys*, and *Stelis*), lay their eggs in the provisioned nests of other insects, whose young are robbed of their food by the earlier hatched intruders, and are consequently starved to death. The wood-wasps (*Crobrionidae*), and numerous kinds of sand-wasps (*Larridae*, *Bembicidae*, *Sphegidae*, *Pompilidae*, and *Scoliidae*), mud-wasps (*Pelopæus*), the stinging velvet-ants (*Mutillidae*), and the solitary wasps (*Odymerus* and *Eumenes*), are predaceous in their habits, and provision their nests with other insects, which serve for food to their young. The food of ants consists of animal and vegetable juices; and though these industrious little animals sometimes prove troublesome by their fondness for sweets, yet, as they seize and destroy many insects also, their occasional trespasses may well be forgiven. Even the proverbially irritable paper-making wasps and hornets (*Polistes* and *Vespa*) are not without their use in the economy of nature; for they feed their tender offspring not only with vegetable juices, but with the soft parts of other insects, great numbers of which they seize and destroy for this purpose. The solitary and social bees (*Andrenidae* and *Apidae*) live wholly on the honey and pollen of flowers, and feed their young with a mixture of the same, called bee-bread. Various kinds of bees are domesticated for the sake of their stores of wax and honey, and are thus made to contribute directly to the comfort and convenience of man, in return for the care and attention afforded them. Honey and wax are also obtained from several species of wild bees (*Melipona*, *Trigona*, and *Tetragona*), essentially different from the domesticated kinds. While bees and other hymenopterous insects seek only the gratification of their own inclinations, in their frequent visits to flowers, they carry on their bodies the yellow dust or pollen from one blossom to another, and scatter it over the parts prepared to receive and be fertilized by it, whereby they render an important service to vegetation.

HYRAX. A curious genus of small rabbit-like animals, inhabiting rocky and mountainous districts in Africa and Syria. The best known species are the Cape Hyrax,

ROCK RABBIT — (HYRAX CAPENSIS.)

which inhabits Southern Africa; and the Syrian Hyrax, which is common to Syria, Arabia, and Abyssinia.—The CAPE HYRAX (*Hyrax Capensis*) resides in the hollows of rocks, leaping with great agility from crag to crag, though its walking or general pace is by no means quick. In size

and colour it greatly resembles the rabbits. It is of a thick form, with short limbs, the hinder being the longest, and it is destitute of a tail. The head is rather small; the ears short and rounded; the eyes large and black; the fore feet have each four soft pulpy toes, with flattish, rounded nails; the hind feet have only three, the inner one of

SKULL AND PART OF SKELETON OF HYRAX.

which is furnished with a sharp crooked claw. Both this and the Syrian Hyrax live in families, and take up their abode in caves or crevices in the sides of rocks. They subsist on grain, fruit, roots, the young shoots of shrubs, herbs, and grass: they are easily tamed, and are lively, active, docile, and cleanly when domesticated. Although the external appearance and the habits of the Hyrax appear to point it out as being a rodent quadruped, Cuvier says that its osteological structure shows it to belong to the *Pachydermata*, and that, notwithstanding the smallness of its proportions, it must be regarded as intermediate between the Rhinoceros and the Tapir. The Syrian species is doubtless "the Coney" of the Scriptures.

HYSTRIX. [See PORCUPINE.]

IBEX. A quadruped of the Goat kind. several distinct species of which are said to exist among the mountain ranges of Europe, Asia, and Africa, most of them resembling

IBEX.

each other in structure and habits. Those best known are the *IBEX CAPRA*, and the

IBEX EGAORUS, or Caucasian Ibex: they are each much larger and stronger than the common domestic Goat; and to the one or the other of these, that animal is believed to owe its origin. The Ibex *Capra* inhabits the Carpathian and Pyrenean mountains, various parts of the Alps, &c. Its colour is a deep hoary brown; the under parts of the body and insides of the limbs being of a much paler or whitish hue: its body is thick, short, and strong; it has a small head; large eyes; strong legs; very short hoofs; and a short tail. The horns, which are extremely large and long, and of a deep brown colour, are marked on the upper surface with protuberant transverse knots or half circles: the hair is harsh; and the male is furnished with a beard. The female is smaller than the male, with smaller horns in proportion, much less boldly knotted. These animals usually resort to the most precipitous heights of lofty mountains, where they assemble in small flocks, sometimes consisting of ten or fifteen individuals. They are remarkably swift, and display amazing agility and dexterity in leaping. They are objects of the chase, but the danger attendant on the pursuit of them is great indeed; for not only are strength, address, and activity necessary to the hunter when following the Ibex from one precipice to another, or in tracking him among difficult passes; but, when close pressed, he will sometimes turn on his pursuer with impetuous rapidity, and hurl him down the most frightful declivity. The fore legs being considerably shorter than the hinder, enables these animals to ascend with more facility than to descend, and hence, when pursued, they always attempt to gain the summits of the mountains. The season for hunting them is during August and September, when they are usually in good condition. The voice of the Ibex is a sharp, short whistle, not unlike that of the chamois, but of shorter duration; sometimes, and especially when irritated, they make a snorting noise. The female has seldom more than one young one at a time; to this she pays great attention, defending it with courage and obstinacy.

The **CAUCASIAN IBEX** (*Ibex Egaorus*) is considerably larger than the Common Goat, and in form bears considerable resemblance to the animals of the cervine genus. It inhabits the loftiest rocky points about Mount Caucasus. Its general colour is a brownish-gray above, and white beneath: the forehead is nearly black: and a black stripe is continued down the back; the horns, which are very large, and bend far backwards, are smooth, black, sharply ridged near the top, and hollowed on their exterior side, but have no appearance of either knots or rings; they are about three feet long, close at the base, about a foot apart in the middle, and eight or nine inches at the tips. The male has a large brownish beard: the female has neither horns nor beard.

One of the handsomest of these animals is the **JEMLAH IBEX**, an inhabitant of the Himalaya Mountains. Its head is finely formed, full of beauty and expression; it has

no beard; and its horns are remarkably massive at the base. It lives solitarily or in small herds; and though bold and pugnacious, it is easily tamed.

IBIS. A genus of birds which in their general habits and conformation closely approach the Storks: they chiefly inhabit warm countries, but, except in very cold regions,

SACRED IBIS.—(*IBIS RELIGIOSA*.)

they are to be found in all parts of the world. Generic characters:—beak arched, long, slender, thick at the base, and quadrangular, rounded at the tip, which is obtuse; nostrils linear, extending from the root to the tip of the beak, and dividing it into three portions, of which the upper is the broadest, and flattened; head and throat bare; legs long, and four-toed, the front webbed at their base as far as the first joint, the hind toe very long, all provided with claws. They frequent the borders of rivers and lakes, feeding on insects, worms, mollusca, and occasionally on vegetable matter. They perform powerful and elevated flights, extending their neck and legs, and uttering a hoarse croak.

THE GLOSSY IBIS (*Ibis falcinellus*) is nearly two feet in length. In the adult bird, the neck, breast, top of the back, and all the inferior parts of the body, are of a bright red chestnut; the wing-coverts, quills, tail-feathers, and the rest of the back, of a dusky green, glossed with bronze and purple; but it varies much in its plumage at different ages. This species builds in Asia, and is found on the streams and lakes, in flocks of thirty or forty. They migrate periodically to Egypt; and in their passage they are numerous in Poland, Hungary, Turkey, and the Grecian Archipelago. They occasionally visit the banks of the Danube, Switzerland, and, more rarely, England and Holland.

THE WHITE IBIS (*Ibis religiosa*) arrives in Egypt about the time that the inundation of the Nile commences, its numbers increasing or diminishing with the increase or

diminution of the waters: and it migrates about the end of June, at which time it is first noticed in Ethiopia. This species does not collect in large flights, more than eight or ten seldom being seen together. They

SKELTON OF WHITE IBIS.

are about the size of a fowl; the head and neck bare; the body white; the primaries of the wings tipped with shining, ashy black, among which the white forms oblique notches; the secondaries bright black, glossed with green and violet; the quill feathers of the tail white. This and the above described were the two species of birds adored by the ancient Egyptians, who used to rear them in their temples, and after death embalm them. Their mummies are found to this day in numbers, in the vast catacombs of ancient Memphis.

IBIS, AS REPRESENTED ON EGYPTIAN MONUMENTS, WITH SECTION OF ITS SKULL.

"This," says Cuvier, "is the most celebrated species: It was reared in the temples of ancient Egypt, with veneration which approached to worship; and it was embalmed after its death, as some said, because it devoured the serpents which would otherwise have become dangerous to the country: according to others, because there was a resemblance between its plumage and some of the phases of the moon: finally, according to a third, because its advent announced the rising of the Nile. For a long time it was thought that this Ibis of the Egyptians was the Tantalus of Africa: we now know it belongs to the genus of which we are treating. It is as large as a hen, with white plumage, except the end of the wing-feathers, which is black; the last coverts have their barbs elongated, loose, black, with violet reflections, and thus covering the end of the wings and tail. The bill and the feet are black, as well as all the naked part of the head and neck: this part is covered in youth, at least in its upper surface, with small blackish feathers. The species is found throughout the extent of Africa."

The SCARLET IBIS (*Ibis rubra*) is a very splendid bird, and is found in the hottest parts of America in large flocks. They fly rapidly, but rarely, except at morning and evening, in search of food. The plumage is scarlet; beak naked; part of the cheeks, legs, and feet, pale red. Before the Scarlet Ibis reaches its full age, its plumage varies considerably.—Other species are found in India, Madagascar, the Cape of Good Hope, and Mexico.

ICHNEUMON. (*Herpestes*.) An animal bearing a very close resemblance to the weasel tribe both in form and habits. From the snout to the root of the tail it is about eighteen inches long: it has a long, agile body, short limbs, semi-plantigrade feet, small glazing eyes, and a pointed nose. It glides towards its prey with a snake-like movement, and then darts suddenly upon it. These animals feed upon birds, reptiles,

ICHNEUMON.—(*HERPESTES ICHNEUMON*.)

rats, mice, &c. Their disposition is as sanguinary as their habits are predatory; but though the destruction they cause among the poultry is very annoying, it is well compensated by the incessant war they wage against reptiles, the eggs of which they devour with the greatest avidity. The most celebrated species inhabits Egypt and the adjacent countries, where it is called "Pharaoh's rat." It is larger than a cat, but formed like a weasel; it is of a gray colour, and has a long tail, terminated by a black

tuft. This species was ranked by the ancient Egyptians among their numerous divinities on account, it is supposed, of the benefits it confers on man by the destruction of crocodiles, whose eggs it digs out of the sand, and sucks. It is also a natural enemy of the whole serpent race, and so exceedingly expert in seizing them by the neck, as to avoid any injury to itself. The Ichneumon is easily domesticated, seeming to form an attachment to its place of residence; and it is not unfrequently kept tame both in India and Egypt, for the purpose of clearing the houses of mice and rats. Ichneumons are sometimes seen to squat on their haunches, and feed themselves with their fore paws, like the squirrel. When they sleep, they bring their head and tail under their belly, and appear like a round ball. In a wild state they generally reside along the banks of rivers; and they swim and dive like the otter, being able to continue under water for a great length of time.

ICHNEUMONIDÆ, or ICHNEUMON-FLIES. A family of hymenopterous insects, the genera and species of which are very numerous, and their manners extremely diversified, but all agreeing in this characteristic—that they deposit their eggs in the bodies of other living insects, and generally in those of caterpillars. The

ICHNEUMON.—(*PIMPLA PERSUSARIA*.)

females have a sharp and strong abdominal tube, or ovipositor, which is used to insert their eggs into the bodies of Caterpillars that live beneath the bark, or in the crevices of wood; this is generally long, and capable of piercing almost any substance: while such as have a short ovipositor, place their eggs in or upon those caterpillars to which they have easy access. These eggs

are in a few days hatched, and the young larvae, which resemble minute white maggots, subsist on the juices of their victim, but without absolutely destroying it: in fact, the animal they infest may continue to exist for some time, thus affording them a continued supply of nutriment; but when the Ichneumons are ready to undergo their last metamorphosis, they pierce the skin, and each spinning itself up in a small oval silken case, changes into chrysalis, the whole number forming a group on the shrivelled body of the caterpillar; and, after a certain period, they emerge in the state of complete Ichneumons. One of the most familiar examples of this process is afforded by the caterpillar of the common white or cabbage butterfly, which in autumn may be frequently observed to creep up some wall or other convenient surface, in order to undergo its own change into chrysalis; but in the space of a day or two a numerous tribe of small maggots will be seen to emerge from it, and immediately proceed to envelope themselves in distinct yellow silken cases; the whole forming a group around the caterpillar. The perfect Ichneumons feed solely upon the juices of flowers, and fly about with considerable agility in search of their food, or of proper situations for the deposition of their eggs.

These carnivorous insects are of various sizes; some are so small, that the Aphis, or plant-louse, serves as a cradle for their young; others again, from their size and strength, are formidable even to the spider, destroying them with their powerful stings; some place their eggs within the aurella of a nascent insect; others deposit them within the nest, which the wasp has curiously contrived for her young; and, as both are produced at the same time, the offspring of the Ichneumon not only devour the young wasps, but the whole supply of larvae which the parent had carefully provided for their support. The best known, and perhaps the most formidable of this genus, is the common Ichneumon with four wings like the bee; a long slender black body; and a three-forked tail, consisting of bristles, of which the two exterior are black, and the central one is red. But when we read that "probably more than 3000 species exist in Europe alone, and the number peculiar to other parts of the globe may fairly be reckoned as at least equal," it would seem to be of little use to attempt to give more than this general description; we shall therefore conclude by remarking, that however terrible to other insect tribes the Ichneumon-flies may be, their destruction of countless myriads, which would otherwise be left to banquet on the fruits of the earth, must be of the most essential service to mankind.

ICHTHYIAETUS. A sub-genus of the Falcon family of birds, so named from their living principally on fish. From the account given in Mr. Gould's work, some members of the genus would seem to partake of the habits of the vulture family; among these is the

ICHTHYIAETUS LEUCOGASTER, or **WHITE-BELLIED SEA EAGLE.** This is a fearless

and familiar bird, found throughout the whole of South Australia. It is distinguished by its never plunging beneath the surface of the water, but living on dead cetacea, fish, &c., left on the shore by the tide. In Bass's Straits it subsists principally on Petrels and Penguins, which are easily captured. On the main land it builds a large flat nest on a fork of the loftiest trees, on islands, on the flat surface of a large stone, and sometimes on the twigs and branches of barilla, a low shrub. One nest was observed on a tree 200 feet high and 41 feet round, where it probably had its nest for several years.

ICHTHYOSAURUS, or FISH-LIZARD.

A genus of extinct marine animals which combined the characters of saurian reptiles and fishes, with some peculiar to cetaceans mammals. This extraordinary creature, whose fossil remains discover its anatomical conformation, has been the subject of much learned investigation; and the anatomy and animal economy of it are in a manner established. Some of the largest exceeded thirty feet in length; and, from their structure, it is easy to conceive that they must have been very formidable enemies to the other inhabitants of the deep. The spinal column was formed like that of a fish, the vertebrae

ICHTHYOSAURUS COMMENS.

being concave on both surfaces, and the arches which enclosed the spinal chord always remained distinct from the bodies as in reptiles; hence the body must have had great flexibility; but the progression of these animals through the water was chiefly by means of the anterior and posterior extremities (of which there were four), formed very much upon the plan of the feet or paddles of the whale. The general form of the head was not unlike that of the porpoise; and it had an elongated and pointed muzzle, the mouth being armed with numerous crocodile-like teeth; and its body terminated in a long and powerful tail. From the absence of any remains of scales or plates, it may be concluded that the skin was naked, like that of the whales and their allies; and that it was an air-breathing animal, coming to the surface of the water occasionally, no doubt exists. From the remains of crushed and partially-digested fish bones and scales which are found with their bones, it appears that the Ichthyosauri principally preyed upon fishes. Dr. Buckland states that the fossil remains of these animals abound along the whole extent of the lias formation, from the coasts of Dorset, through Somerset and Lei-

cestershire, to the coast of Yorkshire. The lias of Germany and France also contains them.

Mr. Pearce found, within a specimen of the Ichthyosaurus, what he thinks may have been an embryo; and although the Ichthyosaurus, by analogy, might have been supposed to be oviparous in its generation, yet Dr. Buckland and Professor Owen think there is no reason why it should not have been viviparous; and from the evidence of Mr. Pearce's specimen it appears fair to suppose that they really were so. The collection of remains of Ichthyosauri in the British Museum is very perfect and great; and with the allied Plesiosauri forms quite a feature in the room devoted to their exhibition.

ICTERIA, or CHATTERING FLY-CATCHER. (*Icteria viridis*.) This bird abounds in most parts of North America during the summer months, and is remarkable both for its colouring and its habits. It is about six inches in length; nearly the whole of the upper parts of its body are of a rich deep olive green, the tips of the wings excepted, which are of a dusky brown: the throat, breast, and sides of the body are of a bright yellow; the belly and vent white; the forehead pale ash; from the nostrils a line of white extends to the upper part of the eyes, which it nearly surrounds; another white spot is situated at the base of the under mandible: beak strong and black; legs and feet pale blue. It has the faculty of mimicking almost any noise that it hears, which it will repeat during the whole night if the weather be fine. Its favourite residence is in close hazel or bramble thickets, and its nest is composed of dry leaves with layers of grape vine bark, lined with fibrous roots and dry grass. The female lays four flesh-coloured eggs, sprinkled with brown and dull red spots.

IGUANA. A genus of Reptiles of which there are several species; the genus including several of large dimensions, common in the tropical parts of America, some of which feed on vegetable substances, and are esteemed delicious food; while there are others which appear to be omnivorous. They are thus characterized by Cuvier:

IGUANA.—(*I. TUBERCULATA*.)

body and tail covered with small imbricated scales: the ridge of the back garnished with a row of spines, or rather of elevated, compressed, and pointed scales; under the throat a depressed and depending dewlap, the edge of which is attached to a cartilaginous

appendage of the hyoid bone. Their tails are provided with a similar arrangement of porous tubercles with the true lizards, and their head is covered with scaly plates. Each jaw is furnished with a row of compressed triangular teeth, having their cutting edges serrated: there are also two small rows on the posterior part of the palate. They live for the most part on trees, but sometimes take to the water, and swim with ease. They attain a great size, being sometimes found five feet in length, though they are much more often from two to three: their upper parts are bluish-green, and sometimes slate colour; the under parts yellowish-green; in general, on the sides of the body are brown stripes or zigzags edged with yellow; and the tail is surrounded with large brown or yellow rings. The Common Iguanas (*Iguana tuberculata*) are eagerly sought, especially in the spring, being esteemed a great delicacy. They are caught by means of a noose attached to the end of a stick: for the animal, though formidable in appearance, is timid and defenceless. It is very active; but when it has taken refuge in a tree, it appears to depend on the security of its situation, and never offers to stir unless roused; hence it is easily taken. The female deposits her eggs, which are about the size of a pigeon's egg, in the sand, where they are left to be hatched by the genial warmth of the sun.

IGUANIDÆ. The family of Saurians, or lizard-like reptiles, of which the animal just described is the type, and of which there are several sub-genera: descriptions of which are given in Mr. Gray's elaborate work, the Catalogue of Lizards in the British Museum. [See LIZARD.]

IGUANODON. The name given to an extinct gigantic reptile, closely resembling the Iguana in osseous structure, whose remains were discovered by Dr. Mantell in the wealden formation of the South of England, in the localities of Furbeck, the Isle of Wight, and Maidstone. From its dentition there seems to be no doubt that it was herbivorous; the form of the teeth, considered with relation to the demands made by the habits of the animal, being well adapted for cropping tough vegetable food, such as the *Clathraria* and similar plants which are found buried with the Iguanodon. From the proportions which the bones of the Iguanodon bear to those of the Iguana, this extinct monster is calculated to have been 70 feet in length from the snout to the end of the tail; the length of the tail alone 52½ feet, and the circumference of the body 14½ feet. The thigh bone of the full-sized Iguanodon is twenty times the size of that of the Iguana; and on the snout of this prodigious reptile was a short but strong horn: its whole appearance, indeed, must have realized the wildest poetical fictions of the dragons of old. In the British Museum are contained all the specimens of Iguanodon obtained by Dr. Mantell; and a comparison of the teeth and bones, with those of its recent comparatively Lilliputian analogue, is a most interesting and curious study.

INCA. A genus of Lamellicorn Beetles, by many authors placed among the Goliath beetles, but whose situation in the system, according to more modern views, is nearer *Trichius*. They are natives of South America. The species figured here is *Inca Weberi*. It is of a violet black; the thorax edged with white; three-banded, the outer bands connected with the white edge of the thorax: the elytra have a reddish tinge, spotted with

WEBER'S INCA BEETLE. — (INCA WEBERI.)

small palish marks. It is a native of South America: and the accompanying figure will show its form and appearance. (See GOLIATH.)

INDICATOR. [See HONEY-GUIDE.]

INDRI. The name of a quadruped belonging to the family *Lemuridae*. It is a native of Madagascar, and from its fine long hair is called *Indris laniger*.

INFEROBRANCHIATA. An order of molluscous animals (Gastropods), characterized by the position of the gills, which are situated beneath the produced margin of the mantle. They are incapable of swimming, and are therefore confined to the sea-shore, where they subsist upon sea-weeds and other aquatic plants.

INFUSORIA. A term applied by naturalists to the numerous minute animals found in water, which are commonly called animalcules. Had the microscope never been invented, the existence of myriads of living creatures whose forms and properties are now in some measure revealed to us, would have been wholly unknown. Ehrenberg, who by means of a most powerful microscope, was enabled to describe species which are not larger than from one-thousandth to two-thousandth of an line in diameter, infers, that a single drop of water may hold 500 millions of these animalcules. By what arithmetical power, then, shall the numbers that swarm in every stagnant pool or lake be calculated? "All true Infusoria," says he, "even the smallest monads, are organized animal bodies (none consisting of

a homogeneous jelly), and distinctly provided with at least a mouth and internal nutritive apparatus." They are found equally abundant as fossils. The Norwegian earth, called *Beergnehl*, or Mountain meal, is principally composed of fossil animalcules. Professor Bailey tells us that the town of Charleston, in the United States, is built upon a bed of animalculæ several hundred feet in thickness, every cubic inch of which is filled with myriads of perfectly preserved microscopic shells. He says also, that these *polythalamia*, or many-chambered shells, to whose labour South Carolina owes so large a portion of her territory, are still at work, in countless thousands, upon her coasts, filling up harbours, forming shoals, and depositing their shells to record the present state of the sea-shore, as their predecessors, now entombed beneath Charleston, have done with regard to ancient oceans. The most highly organized Infusoria are called by Cuvier *Rotifera* (which see).

The immense importance of the Infusoria in the scale of animal existence is chiefly seen by those who visit the Arctic and Antarctic seas. Although remotely supporting the higher animals, yet the want of them would be materially felt. This is well stated by Capt. Sir James Clark Ross, who, in speaking of a small fish found by him in the South Seas, and described by Dr. Sir John Richardson, under the name of *Notothenia pinnæ*, says, "They occupy the place of the *Merlangus polaris* and *Ophidium Parryi*, of the Arctic seas, the latter of which they much resemble; like them, they conceal themselves from the persecutions of their enemies in the small cracks and cavities of the pack ice, and may be seen when driven from shelter by the ships striking and passing over their protecting pieces of ice." The seals and petrels are their chief enemies, whilst they, in their turn, live upon the smaller *Caneri* and *Linnæina*. Thus we behold in these regions, where the vegetable kingdom, which constitutes the support of animal life in milder climates, has no representative, a chain of animal existences, maintained by each preying upon that next below it in the order of created beings, and all eventually nourished and sustained by the minute infusorial animalculæ which we found filling the ocean with an inconceivable multitude of the minutest forms of organic life."—*Antarctic Voyage*, vol. ii. p. 161.

INSECTS. (*Insecta*.) A class of invertebrate animals, to which the term *insecta* has been applied, in reference to the insected, or divided, appearance of the body, which is not only composed of a continuous series of segments, articulating with each other, but is also often divided or cut into three very marked portions, to which the names *head*, *thorax*, and *abdomen* have been applied. There is no class of the animal kingdom which has been the subject of more numerous and various attempts at classification than that of Insects: nor is it at all surprising; since it is pre-eminent in regard to the number of distinct species which it includes, and unsurpassed by any, save the

Infusory Animalcules, in regard to the number of individuals at any time existing on the earth's surface, which belong to the numerous and diversified races comprehended in it. In ordinary phraseology, an Insect may be defined as a little animal without bones or cartilages; furnished with a trunk, or else a mouth opening lengthwise; and with eyes destitute of coverings. This definition will comprehend the whole class of Insects, either with or without wings; either in their caterpillar or perfect state. Every year adds to the difficulty of defining in a brief manner the characters of the great and smaller divisions of the animal kingdom. Hence it will appear, that in this class of animals there are numerous distinctions, and that no general description will serve for all: so various are the appetites, manners, and modes of propagation, that every species requires its distinct history. Though so far inferior in point of magnitude, Insects, it must be confessed, surpass in variety of structure and singularity of appearance all the larger branches of the animal world. The general characters by which they are distinguished from other animals are these:—First, they are furnished with several feet: secondly, the muscles are affixed to the internal surface of the skin, which, though hard, sometimes preserves a certain degree of flexibility: thirdly, they breathe, not like the generality of larger animals, by lungs or gills, but by spiracles or breathing holes, distributed in a series or row on each side the whole length of the abdomen, and communicating with two long air-pipes within their bodies, and a number of smaller ones, to carry the air to every part. The head is furnished with a pair of *antennæ*, or horns, which are extremely various in the different tribes, and which, by their differences of structure, form a leading character in the institution of the genera into which Insects are distributed.

Insects have a very small brain, and instead of a spinal marrow, a kind of knotted cord, extending from the brain to the hinder extremity; and numerous small whitish threads, which are the nerves, spread from the brain and knots, in various directions. The heart is a long tube, lying under the skin of the back, having little holes on each side for the admission of the juices of the body, which are prevented from escaping again by valves or clappers, formed to close the holes within. Moreover, this tubular heart is divided into several chambers, by transverse partitions, in each of which there is a hole shut by a valve, which allows the blood to flow only from the hinder to the fore part of the heart, and prevents it from passing in the contrary direction.

The ancients entertained an idea that Insects were destitute of blood; hence they called them *animalia exsanguinea*: but now they are well known to be so far from bloodless animals, that in many of them the circulation itself of the blood is clearly and distinctly perceived. The blood of Insects differs from that of the larger animals chiefly in colour, since in most insects it wants redness, being generally of a clear or watery

aspect, and sometimes of a yellowish hue. The circulation of the blood is particularly conspicuous in Spiders, and in some species of *Cimex* or bug, especially the *Cimex lectularius*; it is to be observed, however, that it does not circulate in proper arteries and veins; but is driven from the fore part of the heart into the head, and thence escapes into the body, where it is mingled with the nutritive juices that filter through the sides of the intestines, and the mingled fluid penetrates the crevices among the flesh and other internal parts, flowing along the sides of the air-pipes, whereby it receives from the air that influence which renders it fitted to nourish the frame and maintain life.

The first state in which the generality of Insects appear is that of an egg; some few, however, are viviparous. From the egg is hatched the Insect in its Larva state; the Larvæ or Caterpillars of Insects differing materially from each other, according to the different tribes to which they belong. There are some Insects, however, which undergo no change of shape, but are hatched from the egg complete in all their parts, and undergo no farther alteration than that of casting their skin from time to time, till at length they acquire the complete resemblance of the parent animal.

Most insects, in the course of their lives, are subject to very great changes of form, attended by equally remarkable changes in their habits and propensities. These changes, transformations, or *metamorphoses*, as they are called, might cause the same insect, at different ages, to be mistaken for as many different animals. For example, a caterpillar, after feeding upon leaves till it is fully grown, retires into some place of concealment, casts off its caterpillar-skin, and presents itself in an entirely different form, one wherein it has neither the power of moving about, nor of taking food; in fact, in this, its second or chrysalis state, the insect seems to be a lifeless oblong oval or conical body, without a distinct head, or movable limbs; after resting awhile, an inward struggle begins, the chrysalis-skin bursts open, and from the rent issues a butterfly, or a moth, whose small and flabby wings soon extend and harden, and become fitted to bear away the insect in search of the honeyed juice of flowers and other liquids that suffice for its nourishment.

In the different tribes of Insects the Pupa or Chrysalis differs almost as much as the Larva. In most of the Beetle tribe it is furnished with short legs: in the Butterfly tribe it is perfectly destitute of all appearance of legs, and has no other motion than a mere writhing when touched: in the Locust tribe it differs very little from the perfect Insect, except in not having the wings complete: and in most of the Fly tribe it is perfectly oval, without any apparent motion, or distinction of parts. The Pupæ of the Bee tribe, and other Insects of a similar cast, are less shapeless than those of Flies, exhibiting the faint appearance of the limbs: while those of the Libellulæ or Dragon-flies are locomotive, as in the Locust tribe, but differ most widely from the appearance of the complete

Insect, and may be numbered among the most singular in the whole class of Insects. From the Pupa or Chrysalis at length emerges the Insect in its complete or ultimate form, from which it can never change, nor can it receive any further increase of growth.

Hence there are three periods in the life of an insect, more or less distinctly marked by corresponding changes in the form, power, and habits. In the first, or period of infancy, an insect is technically called a *larva*, a word signifying a mask, because therein its future form is more or less masked or concealed. This name is not only applied to grubs, caterpillars, and maggots, and to other insects that undergo a complete transformation, but also to young and wingless grasshoppers, and bugs, and indeed to all young insects before the wings begin to appear. In this first period, which is generally much the longest, insects are always wingless, pass most of their time in eating, grow rapidly, and usually cast off their skins repeatedly. The second period, wherein those Insects that undergo a partial transformation, retain their activity and their appetites for food, continue to grow, and acquire the rudiments of wings, while others, at this age, entirely lose their larva form, take no food, and remain at rest in a deathlike sleep,—is called the *pupa* state, from a slight resemblance that some of the latter present to an infant trussed in bandages, as was the fashion among the Romans. The pupæ from caterpillars, however, are more commonly called *chrysalids*, because some of them, as the name implies, are gilt or adorned with golden spots; and grubs, after their first transformation, are often named *nymphs*; the reason for which is not very obvious. At the end of the second period Insects again shed their skins, and come forth fully grown, and (with few exceptions) provided with wings. They thus enter upon their last or adult state, wherein they no longer increase in size, and during which they provide for a continuation of their kind. This period usually lasts only a short time, for most Insects die immediately after their eggs are laid. Bees, wasps, and ants, however, which live in society, and labour together for the common good of their communities, continue much longer in the adult state.

Insects possess some particular parts which are not to be found in any of the larger animals: among these are the *antennæ* before mentioned, which are those processes or jointed bodies situated on each side the head. They differ extremely in the different tribes of Insects, and are found to constitute one of the most convenient parts to fix upon in the distribution of Insects into genera and species. It is therefore necessary slightly to enumerate some of them:—*Antenna setacea*, or setaceous antenna; bristle-shaped; or growing fine and sharp at its termination; *antenna filiformis*, or thread-shaped, being of equal size throughout; *antenna moniliformis*, or moniliform; each joint being globular, or nearly so; *antenna clavata*, club-shaped; having a knob at the top, as in the major part of Butterflies; *antenna fissilis*, or fissile; one which is split or divided at the tip into

several lamellæ or flat separations: *antenna pectinata*, or pectinated; one which is divided along each side into numerous processes in a comb: *antenna barbata*, or bearded; one which is slightly feathered, either on one or both sides, with fine lateral fibres or hairs: *antenna perfoliata*, perfoliate; the joints of a flattened and circular shape, with the stem or body of the antenna passing through them, as in the leaves of some plants, in which the stem seems to pass through them. Another part peculiar to Insects consists in a pair or two of short jointed processes proceeding from the mouth: these are termed *palpi*, or feelers, which in some Insects are very conspicuous, but not in all. The mouth in Insects is generally situated at the lower part of the front, and varies much in structure in the different orders. In some it is furnished with very strong jaws, often notched or serrated on the inner side into the appearance of teeth, and which always meet horizontally; in others the mouth consists of a tube or instrument for suction, either simple, or guarded by various kinds of appendages. The eyes in Insects are commonly situated on each side of the head, and are two in number; but in some Insects, as in Spiders, there are six or eight. In most of the Insect tribes the eyes may be considered as compound, the cornea presenting when viewed with a microscope the appearance of an infinite number of separate convexities, like so many real convex lenses. There are also on the heads of many Insects three small, smooth, lucid globules resembling so many separate eyes, placed on the top of the head, between or above the lateral ones; these Linnæus distinguishes by the title of *stigmata*; they are also called *ocelli*. The body in the major part of Insects is divided into the thorax or upper part, and the abdomen or lower part. In many of the Beetle tribe the back of the thorax is distinguished by a small triangular piece or division, situated at its lower part, between the juncture of the wing-sheaths: this triangular part is called *scutellum*, or the escutcheon. The under part of the thorax is called the breast, or *pectus*, and in this the sternum is frequently distinguishable. The abdomen is marked into transverse sections, and the last joint terminates in the tail. The wing-sheaths or shelly coverings, in the Beetle tribe and some others, are termed *elytra*.—The name of the orders into which Insects are divided, as *Coleoptera*, *Hymenoptera*, *Diptera*, *Neuroptera*, &c., have reference chiefly to the number and nature of their wings; but as the definitions will be found under their respective names, we need not here repeat them.

In the Introductory Letter to "Kirby and Spence's Entomology," the beauties of the Insect world are thus graphically portrayed:—"Insects, indeed, appear to have been Nature's favourite productions, in which, to manifest her power and skill, she has combined and concentrated almost all that is either beautiful and graceful, interesting and alluring, or curious and singular, in every other class and order of her

children. To these her valued miniatures she has given the most delicate touch and highest finish of her pencil. Numbers she has armed with glittering mail, which reflects a lustre like that of burnished metals; in others she lights up the dazzling radiance of polished gems: some she has decked with what looks like liquid drops, or plates of gold and silver; or with scales or pile, which mimic the colour and emit the ray of the same precious metals. Some exhibit a rude exterior, like stones in their native state; while others represent their smooth and shining face after they have been submitted to the tool of the polisher: others, again, like so many pigmy Atlases bearing on their backs a microcosm, by the rugged and various elevations and depressions of their tuberculated crust, present to the eye of the beholder no unapt imitation of the unequal surface of the earth, now horrid with misshapen rocks, ridges, and precipices—now swelling into hills and mountains, and now sinking into valleys, glens, and caves; while not a few are covered with brancing spines, which fancy may form into a forest of trees. . . . The sight indeed of a well-stored cabinet of Insects will bring before every beholder not conversant with them, forms in endless variety, which before he would not have thought it possible could exist in nature, resembling nothing that the other departments of the animal kingdom exhibit, and exceeding even the wildest fictions of the most fertile imagination."

Before we close this article, we beg leave to quote from Mr. Newman's work on "The History of Insects," the following brief but admirable summary:—"The senses of insects are, properly speaking, seven: love, touch, taste, smell, hearing, sight, and the commanding and governing sense, called volition, mind, thought, or instinct. Love is that sense which ensures obedience to the great command, 'Increase and multiply': its gratification seems the great object of an insect's life, after having arrived at maturity: its seat is in the organs of generation. Touch is a most invaluable sense to insects; they have two antennæ and four feelers attached to the mouth, which appear provided purposely for the exercise of this sense: the tarsi are also employed to ascertain qualities by touch; but the other parts of the body appear insensible to feeling, either as regards the ascertaining of qualities or the sensation of pain. Taste is undoubtedly possessed by insects in an eminent degree; and they seem to have the same preferences for animal or vegetable food which are evinced by vertebrated animals. Smell appears to be the sense by which insects are led to discover strongly-scented substances at a great distance, where it is quite impossible that sight should aid them; its seat, however, is wholly unknown. Hearing seems also to be possessed by insects, or to what purpose would the merry cricket sing his evening song, if there were none of his kind to listen to and admire it? The seat of this sense is also wholly unknown. Sight is a sense of which we have abundant evidence; it is seated in two large compound

eyes, often occupying nearly the whole head, and also occasionally in three minute simple eyes, situated in a triangle on the crown of the head. The mind of insects is more wonderful than our own: it has neither speculation, retention, judgment, nor power: it is, in fact, an existence which comes perfect from the Creator: the newborn bee is perfectly mistress of architecture; she is heaven-instructed: the mind is not only the ruling sense, but is a distinct immaterial element."

INSECTIVORA. The fourth Order of of Mammiferous animals, comprising the Shrews, Hedgehogs, Moles, &c. As the name denotes, they subsist principally on insects, worms, &c. In general they lead a nocturnal and subterranean life; and in cold countries most of them pass the winter in a torpid state. Their legs are short, and in running they place the entire sole of the foot upon the ground. There is great variety in the front teeth of the animals belonging to this Order; in some the canine teeth are longer than the incisors, while in others the canines are very small or entirely wanting. The Order is naturally divided into those with simple fore legs, and those in which the fore legs are peculiarly fitted for digging. The first division comprises the Hedgehogs, the Tenrecs or Madagascar Hedgehogs (which have the muzzle very long, and have not the power of rolling themselves into a ball), the Shrews, and the Desmans (*Sorex moschatus*), a curious tribe of aquatic animals, with webbed feet, and the nose so much prolonged as to look like a proboscis. The second division comprises the Moles, the Shining or Cape Moles (the only quadrupeds whose fur has a metallic gloss), the Radiated Moles, and the *Scalops* or Shrew Mole of the United States. [See MOLE: HEDGEHOG: SHREW, &c.]

INSESSORES. The name given by Mr. Vigors to a most extensive order of Perching Birds; in which are comprehended all those tribes which live habitually among trees, with the exception of the birds of prey and the climbing birds. In all the true Insectorial Birds, the toes are three before and one behind. The adaptation of the foot of this order to grasping or perching is evident from the situation of the hinder toe; which is invariably placed on the same level with those in front; and by which they are distinguished from the Gallinaceous and Wading Birds. The toes are slender, flexible, and of moderate length, with long, slender, and slightly curved claws; of which the foot of the Canary affords a very good example. The birds of this order are generally on the wing; and we accordingly find that, in proportion as the legs are small and weak, the wings are highly developed. The male is nearly always larger than the female, and is more distinguished for the brilliancy of his plumage. The Perchers live in pairs, and construct their nests, usually in trees, bushes, &c., with great art. This order is divided, by the form of the beak, into four subordinate groups; namely—1. *Contrastres*, or couical-billed birds;

the greater part of which are omnivorous, though some are exclusively granivorous, 2. *Dentirostres*, or tooth-billed birds; which are characterized by a tooth or notch near the extremity of the upper mandible; these feed on insects, small birds, &c. 3. *Tenuirostres*, or slender-billed birds: these have a long slender bill, adapted for sucking up vegetable juices, &c.; and to this group belong also many whose principal food consists of insects. 4. *Fissirostres*, or gaping-billed birds; in which the beak is very much flattened, in order to afford them greater facility for capturing insects when on the wing, as is seen in the swallow and others of that kind.

INTESTINALIA. Another name for those parasites, worms, or *Entozoa*, which infest the intestinal canal of the higher animals. There are four orders; viz. 1. *Nematoidea* (Round-worms); 2. *Acanthocephala* (Hooked-worms); 3. *Trematoda* (Fluke-worms); 4. *Cestodea* (Tape-worms). The *Hydatids* or *Cystic-worms* are only the young of the last-named order.

IRIDINA. A genus of *Conchifera*, consisting of one species only, the *Iridina cratrea*, which is found in the Nile, and in many other rivers of warm climates. The shell is equilateral and inequilateral; teeth very small and numerous; inside very iridescent and of a red cast; ligament external; the hinge lamina crenulated in its whole length. It is used by the natives of Egypt as spoons in measuring oil, butter, and different kinds of provisions.

ISOCARDIA. A genus of *Cancellifera*, the shells of which are remarkable for the beautiful curvature of the diverging umbones.

ISOPODA. The name of an order of aquatic Crustacea, many of which are parasitic upon other animals, very frequently upon larger crustacea.

IULUS, or JULUS. The *Julidae* are a family of *Myriapoda*, very nearly allied to the *Centipedes* (*Scolopendree*); but their body, instead of being flattened, as in that genus, is nearly cylindrical. Each of the numerous segments of the body is furnished with two pair of feet or legs, which are scarcely large or strong enough to support its weight; so that the animal, instead of appearing to walk, seems to have a sort of undulatory motion, like a serpent or worm. They roll themselves up in a spiral form; and the firmness of the rings of the body enables them to resist considerable pressure. The eyes of the *Julidae* are composed of nu-

they usually feed. Some are found under stones, others in the earth, and some inhabit nuts. The most common species is the *Julus sabulosus*, about an inch and a quarter in length: its colour is a polished brownish black, with whitish legs: it is oviparous, and the young, when first hatched, have only three pair of legs, which are situated near the head; the remainder being gradually acquired till the number is complete, which usually amounts to a hundred and twenty on each side. In its young or growing state, it is of a pale colour, with a dark red spot on each side of every segment; and in this state it may sometimes be found in the soft mould of hollow trees.—The largest species known is the *Julus Iulus*, or *Julus maximus*, which in its conformation resembles the species above described, but is from six to seven inches long. This is found in South America and the warmer parts of Asia, inhabiting woods and other retired places. The *Julidae* have no poisonous organs, and are perfectly innoxious to man; indeed, by their consuming vegetable substances that are in a state of decomposition, they may be considered beneficial. Mr. Newport, F.R.S., has made them and the *Scolopendridae* a special object of study, and has published the results in the *Linnean Transactions*. In the British Museum there is a very extensive collection of these interesting *Myriapoda*. [See *CHILognATHA*.]

JABIRU. A large aquatic bird, allied to the stork, three species of which are known, respectively inhabiting America, Western Africa, and Australasia. It is the *Mycteria* of Linnaeus. It is somewhat larger than the swan; the head is large; the neck thick;

SYNGAL JABIRU.
(MYCTERIA SENEGALENSIS.)

GIANTIO MILLIPÈDE.—(JULUS MAXIMUS.)

merous hexagonal convexities, as in the greater part of the insect tribes; and the mouth resembles that of the larvæ of many insects by being furnished with a pair of denticulated jaws; by means of which they are enabled to divide with facility the portions of decaying vegetable matter on which

and the bill is long, conical, smooth, and pointed. The body is entirely white; the head and neck are very bare of feathers, and covered with a thick black skin; and the tail is broad and short: the legs, which are more than two feet long, are thick and scaly; and the bill and feet are black. Our figure represents a gigantic species from the west coast of Africa, the *Myetaria fenegalensis*, on the shore of which it must form a striking feature. In the enormous size of the beak this species resembles the Adjutant of India, and like that bird, we suppose this species to be somewhat of a carrion eater.

JACAMAR. (*Galbula*.) The birds belonging to this genus, of which there are but a few known species, are very much allied to the Kingfishers, except that their feet are quite different, and they inhabit moist woods; whereas the Kingfishers are only found on or near the banks of rivers. Their plumage has a metallic lustre, which it is extremely difficult to imitate.

The **GREEN JACAMAR** (*Galbula viridis*) is a splendid bird, about the size of a lark; its prevailing colour on the upper parts of the body being a most brilliant, changeable green, glossed with copper and gold. The beak is about two inches in length, black, slightly incurved, and sharp-pointed; the legs, which are short and weak, are a greenish yellow; and the claws black. Its breast and belly are of a dusky yellow hue, and the chin white. The tail is wedge-shaped; the two middle feathers very long, and the outer ones much shorter. The habits of this

GREEN JACAMAR.—(*GALBULA VIRIDIS*.)

bird are very solitary; it resorts to the thickest parts of the woods, where it can obtain plenty of insects, and is seldom seen in company with another. Its flight is short and quick; and it is said to have an agreeable note.

The **PARADISE JACAMAR** (*Galbula paradisæa*) is a less solitary bird than the others of this genus; being found in pairs, and frequenting the more open parts of the woods. It is nearly a foot in length: beak two and a half inches long, black, pointed, square, and compressed on the sides: head of a dull violet green; throat, fore part of the neck, and under wing-coverts white; the rest of the plumage green, varying in shades and glosses according to the lights in which it is viewed; the two middle tail-feathers six inches long, and the outer one only an inch: legs black. Native of Surinam and Cayenne.

JACANA. A genus of wading birds, distinguished by the extraordinary length of their toes and their spine-like claws, especially that of the hinder toe. They are very light birds; and the wide surface over which their toes extend, enables them the more easily to procure their food, consisting of worms, small fishes, and insects, by walking on the leaves of aquatic plants which float on the water. Various species of the Jacana, which in contour and habit resemble our moor-hen, are spread over the tropical regions both of the Old and New World.

The **COMMON JACANA** (*Parra Jacana*) is about ten inches long, the beak being upwards of one inch, and orange-coloured: the head, throat, neck, breast, and under parts are black; the back, wing-coverts, and scapulars bright chestnut; spur on the wing yellow, and the bend of the wing varied with black: the quills olive-yellow, tipped and partly edged with dusky; tail rounded, chestnut tipped with black; legs greenish ash. These birds inhabit Brazil, Surinam, and other parts of South America and the West Indies: they are very shy and noisy, and their note is very shrill.

The **INDIAN JACANA** (*Parra Indica*) is a shy bird, frequenting stagnant lakes, and building its nest upon floating materials, among weeds, near the banks. It has a yellow beak, with the base of its upper mandible dusky blue; and near the gape a red spot: over the eye is a white streak, which reaches some distance down the side of the neck: the head, neck, and upper parts of the body are deep blue-black; the back and wings are ashy-brown; legs dirty yellowish-brown.

The **BRONZED JACANA** (*Parra onca*) is a highly elegant species inhabiting Brazil. The prevailing colour of the body is black, brilliantly glossed with blue and violet reflections; its head and neck are of a brilliant bronzed-green colour: behind the eye is a white streak: the quills are black; the wing-coverts dull yellow; and the rump and tail are blood-red.

JACCHUS, or **MARMOZET**. A genus of Monkeys, of a small size, with short muzzle, flesh-coloured face, and round head. The five fingers are armed with claws, except the thumbs of the posterior extremities, which have nails: fur very soft; tail full and handsome. Length of body about eight inches; tail eleven. General colour olive-gray; head and shoulders nearly black; the tail and lower part of the back are annulated with pale gray; and two tufts of pale hair grow round the ears. They are squirrel-like in their habits, and omnivorous; feeding on roots, seeds, fruits, insects, snails, and young birds. Native of Guyana and Brazil.

JACK. [See **PIKE**.]

JACKAL. (*Canis aureus*.) This animal in its appearance somewhat resembles the fox, while its habits are more like those of the wolf. It is a native of India, Persia, and various other of the warmer parts of Asia, as also of Barbary, and the interior of South

Africa. Its sire is about that of a fox, but longer in the legs; its colour a light orange-yellow or yellowish gray above, and whitish below, with dark shades about the back: the

JACKAL.—(CANIS AUREUS.)

tail hangs straight, is rather bushy, and generally black at the tip: the ears are very ruddy, and the muzzle pointed. The voice of the Jackal is described as peculiarly hideous, consisting of an indistinct bark and a piteous howl. It resides in woods, holes, and rocky places; and preys indiscriminately on all the weaker animals, committing ravages among flocks, in the poultry-yard, &c., though it seldom ventures abroad till nightfall. Jackals frequently go in great troops to hunt their prey, and by their dreadful yellings alarm and put to flight deer, antelope, and other timid quadrupeds; while the Lion, instinctively attending to the clamour, is said to follow till the Jackals have hunted down the prey, and, having satiated himself on the spoil, leaves only the scanty remains to the famished hunters. Hence the Jackal has been popularly called "the lion's provider." Some say that the Jackal has a natural propensity to follow mankind, instead of flying from him, like the Wolf and the Fox: also that the whelp is readily tamed, and, when grown up, assumes all the habits of the domestic Dog; nay, it is well known that the Jackal interbreeds with the common dog; its period of gestation is the same, and the hybrid progeny is fertile. We should, however, observe, that between the Jackal and the Dog there exists such an irreconcilable antipathy, that they never meet without a combat.

JACKDAW, or DAW. (*Corvus monedula*.) A well-known English bird, considerably less than the Rook, being about thirteen inches in length, and twenty-eight in breadth. The bill and legs are black; the claws strong and hooked; eyes white; the hinder part of the head and neck is silvery gray; the rest of the plumage is of a fine glossy blue-black above, beneath dusky. Jackdaws frequent church steeples, old towers, and ruins, in flocks, where they build their nests: the female lays five or six eggs, paler and smaller than those of the crow. They are easily tamed, and may be taught, like the magpie, &c., to imitate human articulation: they have also the mischievous faculty of stealing and hiding money, spoons, or other glittering and metallic substances. They feed on insects, grain, fruit, small pieces of flesh, eggs, &c. They remain in this country during the whole year; but in France, Germany, and other parts of the Continent, they are migratory. From an article, headed "Habits of the Jackdaw," in Mr. Waterton's

Essays, we glean the following observations: "Though the Jackdaw makes use of the same kind of materials for building as those which are found in the nest of the rook; though it is, to all appearance, quite as hardy a bird; and though it passes the night, exposed to the chilling cold and rains of winter, on the leafless branches of the lofty elm; still, when the period for incubation arrives, it bids farewell to those exposed heights, where the rook remains to hatch its young, and betakes itself to the shelter which is afforded in the holes of steeples, towers, and trees. Perhaps there is no instance in the annals of ornithology which tells of the Jackdaw ever building its nest in the open air. Wishing to try whether these two congeners could not be induced to continue the year throughout in that bond of society which, I had observed, was only broken during incubation, I made a commodious cavity in an aged elm, just at the place where it had lost a mighty limb, some forty years ago, in a tremendous gale of wind which laid prostrate some of the finest trees in this part of Yorkshire. At the approach of breeding-time, a pair of Jackdaws took possession of it, and reared their young in shelter; while the rooks performed a similar duty on the top of the same tree, exposed to all the rigours of an English spring. This success induced me to appropriate other conveniences for the incubation of the Jackdaw; and I have now the satisfaction to see an uninterrupted fellowship exist, the year throughout, between the Jackdaw and the Rook."

JAGUAR, or OUNCE. (*Felis onca*.) A fierce and destructive animal of the feline kind, partaking of the qualities and habits of the Tiger: it is a native of the hotter parts of South America, and from its being the most formidable quadruped there, is sometimes called the tiger or panther of the New World. It is as large as a wolf, and lives solely on prey. Its ground colour is a pale brownish yellow, variegated on the upper parts of the

JAGUAR.—(FELIS ONCA.)

body with streaks and irregular oblong spots of black; the top of the back being marked with long uninterrupted stripes, and the sides with rows of regular open marks; the thighs and legs are marked with full black spots; the breast and belly are whitish; the tail not so long as the body; the upper part irregularly marked with large black spots, the lower with smaller ones. It swims and climbs with ease; and preys not only on the larger domestic quadrupeds, and on smaller

that are wild, but also on birds, fish, tortoises, turtles' eggs, &c. It must, however, be very hard pressed before it will attack man.

JANTHINA. A Molluscous animal, belonging to the *Pectinibranchiata*. The shell has some resemblance to our land snails, but the aperture is angular at its lower part and at its outer side, where, however, the angle formed by the union of the upper and lower halves of the outer lip is much rounded in most of the species; the columella straight

PURPLE SEA SNAIL.—(*JANTHINA COMMUNIS*.)

and elongated, the inner lip turned back over it. The animal has no operculum, but carries under its foot a vesicular organ, like a congeries of foam-bubbles, of solid consistence, that prevents creeping, but serves as a buoy to support it at the surface of the water. The head is a cylindrical proboscis; and is terminated with a mouth cleft vertically, and armed with little curved spines: on each side of it is a forked tentaculum. The shells are of a violet colour; and when the animal is irritated it pours forth an excretion of deeper blue to tinge the sea around it.

"The method in which this animal fills its float," says Capt. Grey, "is curious: it throws it back, and gradually lifts the lip of the valve out of water, until the valve stands vertical; it then closes the valve tightly round a globule of air, around which it folds, by means of the most complex and delicate machinery. The valve is then bent over until it touches the edge of the float nearest the head, and when it is in this position, the portion of it which is inflated with air looks like a bladder, the air gradually is expelled into the float, and as this process takes place the bladder in the valve diminishes, and the valve becomes by degrees like a lip pushed forwards until it lies flat on the float: the valve is composed of two portions, a cup and a lip. The time occupied from first removing the valve from the float, until the inflation, and the expulsion of air into the float being completed, so that the valve begins to move again, is sixty-one seconds, from the mean of several experiments. These animals have also the power of compressing the valve into a hollow tube, which they elevate above the water like a funnel, and draw down air through it. The colouring matter which they emit has no stinging, electric, or deleterious properties whatever, that I could discover. I found that when this colouring matter was mixed with water, it became of a deep blue. In those which I caught in Nov. 1837, I may have been deceived, and

the colouring matter might also possibly have been scarlet directly it was emitted. It is difficult to conceive what use this liquid can be to the fish against its foes, yet it certainly uses it as a means of defence. To one of these shells, the fish in which was alive and well, we found attached a number of barnacles, some of which were of large size."—*Narrative of Expedition in South Australia.*

JAY. (*Garrulus glandarius*.) The Jay is the most elegant bird of the Corvine genus in Britain, and is about thirteen inches in length. Its general colour is a light purplish buff, paler on the under parts; the wings black, with a large white spot in the middle: its bill and tail are black; the former notched on each side near the tip, and the latter rather rounded at the end: the feathers on the forehead are white, streaked with black, and form a tuft which it can erect or depress at pleasure; the greater wing-coverts are elegantly barred with black, fine pale blue, and white alternately; the lesser wing-coverts bay; the belly and

JAY.—(*GARRULUS GLANDARIUS*.)

vent almost white: the greater quills are black, with light edges; the bases of some of them white; lesser quills black; those next the body chestnut; legs of a dirty flesh colour. The Jay is very common in this country, and is found in most of the temperate parts of Europe, frequenting woods, and feeding on acorns, beech-mast, berries, and fruits of various kinds, insects, and sometimes young birds in the absence of the old ones. The Jays are distinguished as well for the beautiful arrangement of their colours, as for their harsh, grating voice, and petulant, restless disposition. In confinement, however, it loses the beauty of its plumage, and becomes of a dull or brownish tinge. When an owl or other bird of prey appears in the woods, they utter piercing cries, and assemble in great numbers to attack the common enemy: the same thing takes place when they see a sportsman, whom they often frustrate by their vociferous noise. Like their kindred, the magpie and juckdaw, they can be taught a variety of words and sounds, particularly those of a harsh and grating character, as that of a saw, &c. They sometimes assemble in great numbers in the spring, and seem to hold a conference, (as Bewick says) probably for

the purpose of pairing and of fixing upon the districts they are to occupy; and the noise made on these occasions may be aptly compared to that of a distant meeting of disorderly drunken persons. The Jay builds in woods, and makes an artless nest, composed of sticks, fibres, and slender twigs; lays five or six eggs, ash-gray, mixed with green and faintly spotted with brown.

In the 'Journal of a Naturalist' we find, in reference to the love of offspring, as being particularly manifested in birds, the following remarks on the Jay. "This bird is always extremely timid and cautious, when its own interest or safety is solely concerned; but no sooner does its hungry brood clamour for supply, than it loses all this wary character, and it becomes so bold and impudent thief. At this period it will visit our gardens, which it rarely approaches at other times, plunder them of every raspberry, cherry, or bean, that it can obtain, and will not cease from rapine as long as any of the brood or the crop remains. We see all the nestlings approach, and, settling near some meditated scene of plunder, quietly await a summons to commence. A parent bird from some tree surveys the ground, then descends upon the cherry, or into the rows, immediately announces a discovery by a low but particular call, and all the family flock into the banquet, which having finished by repeated visits, the old birds return to the woods, with all their chattering children, and become the same wild cautious creatures they were before."

THE BLUE JAY. (*Garrulus cristatus*.) This elegant species is a native of North America, considerably smaller than the European Jay, with a tail much longer in proportion; the head is handsomely crested, with loose silky plumes; bill black; legs brown; the whole bird is of a fine blue colour on the upper parts, with the wings and tail marked by numerous black bars; neck encircled with a

BLUE JAY.—(*GARRULUS CRISTATUS*.)

black collar; under parts blossom-colour, with a slight cast of blue; tail tipped with white; legs, feet, and thighs of a dusky brown. Its note is less discordant than the

European Jay; but its manners are very similar. It is said to be a great destroyer of maize or Indian corn, often assembling in large flocks to devour it.

Mr. Gosse, in his 'Canadian Naturalist,' thus speaks of this bird, in his observations made during the month of December. "The Blue Jay continues as numerous and as noisy as ever. His harsh screaming voice may be heard above that of all the other feathered inhabitants of our groves, all the year through. A beautiful bird he is, with his bright violet, white, and sky-blue coat, long tail, and pointed crest; and by his airs and grimaces he appears to have no mean idea of his own personal attractions, and probably he may think his voice as charming as his plumage, as he so continually gives us the benefit of his music. He appears to tyrannize over his brethren occasionally. I once saw, in the south, a Blue Jay in close and hot pursuit of a summer Red-bird (*Tampræstiva*), and Wilson records a parallel incident. He has other notes, besides his common loud squall, some of which are difficult to recognize. In the clearing, the parties of these birds, for they are hardly numerous enough to be called flocks, generally fly high, and alight about the summits of lofty trees; but in the woods, particularly in spring, they as frequently choose a lower altitude. They are wary, and rather difficult of approach."

JELLY-FISH. Under the heads "Acalepha," "Berber," and "Medusa," will be found various information applicable to the present article, the popular name of "Jelly-fishes" being very generally used (by the unscientific) to denote the different marine substances forming that branch of the division *RADIATA* which is comprised in the class *Acalepha*. Extreme delicacy of structure is common to the whole group; most of them have no hard support whatever, and the animals when removed from their natural element wholly lose their form; but there are a few species which have a very thin cartilaginous covering, and these retain a semblance of the animal as it appeared when alive. We find that in every climate the ocean swarms with infinite multitudes of animals, which, from their minuteness and transparency, would be almost imperceptible, were it not for the phosphorescent properties of some of them being rendered evident on the slightest agitation. All, however, are not equally minute: some grow to a large size, and their forms are perfectly well known to the casual observers of marine substances which lie on every beach. Most of these are highly phosphorescent; and in tropical regions, more particularly, where they exist in the greatest abundance, the path of a vessel is marked by a brilliant line of glowing light, and the whole surface of the ocean often displays a beautiful luminosity. Even on our own coasts a similar effect is very frequently observed, though the luminous appearance is vastly less brilliant.

In Patterson's "Introduction to Zoology" we find the following practical observations:—"Our admiration for the various func-

tions performed by the *Aculephæ* is much increased when we reflect upon the extremely small quantity of solid matter which enters into their composition. This fact admits of easy illustration, both in the Beroes and in the Medusæ. On one occasion, we took a dead Cydippe, and placing it on a piece of glass, exposed it to the sun. As the moisture evaporated, the different parts appeared as if confusedly painted on the glass; and when it was become perfectly dry, a touch removed the only vestiges of what had been so lately a graceful and animated being. With regard to the Medusæ, we may mention an anecdote which we learned from an eminent zoologist [the late Edward Forbes, F.R.S., Professor of Natural History in the University of Edinburgh]. He had, a few years ago, been delivering some zoological lectures in a seaport town in Scotland, in the course of which he had reverted to some of the most remarkable points in the economy of the *Aculephæ*. After the lecture, a farmer who had been present came forward, and inquired if he had understood him correctly, as having stated that the Medusæ contained so little of solid material that they might be regarded as little else than a mass of animated sea-water? On being answered in the affirmative, he remarked, that it would have saved him many a pound had he known that sooner, for he had been in the habit of employing his men and horses in carting away large quantities of jelly-fish from the shore, and using them as manure on his farm, and he now believed they could have been of little more real use than an equal weight of sea-water. Assuming that so much as one ton weight of Medusæ recently thrown on the beach had been carted away in one load, it will be found that, according to the experiments of Professor Owen, the entire quantity of solid material would be only about four pounds of avoirdupois weight, an amount of solid material which, if compressed, the farmer might, with ease, have carried home in one of his coat-pockets." [For development, &c., see STROBILA in SUPPLEMENT.]

JERBOA. (*Dipus*.) A genus of Rodents between the Squirrels and the Rats, but agreeing with the latter rather than the former; while the enormous development of its hind legs and tail cause it to bear considerable resemblance in form to the Kangaroo. One species is a native of Egypt, Syria, &c.; and was known to the ancients under the name of *Dipus*, (two-footed,) which is still its scientific appellation. The most common species is the *Dipus sagitta*. It is of a pale yellowish fawn-colour on the upper parts, and white beneath; the length of the body is about eight inches, and of the tail ten, being terminated by a tuft of black hair, the tip of which is white, but the rest short and rough. The head is short; the ears thin, broad, upright, and rounded; the eyes large, round, and dark coloured; the fore-legs about an inch long, with five toes to each foot, the inner toe very small, but furnished with a sharp, crooked claw like the rest; the hind-legs are extremely long, thin, sparingly co-

vered with short hair, and very much resemble those of a bird: the hind feet have three toes on each, the middle of which is somewhat larger than the rest, and all are

JERBOA.—(*DIPUS SAGITTA*.)

furnished with sharp and strong claws: there is also a very small spur or back toe, with its corresponding claw. On each side the nose are several long hairs or whiskers; and the cutting teeth are sharp and strong, resembling those of a rat. In its attitudes and manner of progression this animal much resembles a bird; generally standing, like the Kangaroo, on its hind feet, and leaping with much celerity, and to a great distance. It principally uses the fore legs in feeding, putting to his mouth the ears of corn, and various other vegetable substances on which it feeds.

The Jerboas inhabit dry, hard, and clayey ground, in which they make their burrows. These are of considerable length, and run obliquely and winding; at about half a yard below the surface of the ground, they terminate in large excavations or nests; they are usually provided but with one opening, though the animals are provident enough to make another passage, to within a short distance from the surface, through which they rapidly penetrate in case of necessity. They keep within their holes during the day, sleeping rolled up, with their head between their thighs: at sunset they come out, and remain abroad till morning. From the rapidity with which they take their leaps (of six or seven feet at a time), it is nearly impossible to overtake them. In leaping, they carry their tails stretched out; but in standing or walking, they carry them in a curved form, the lower curve touching the ground. In their wild state these animals are very fond of bulbous roots; but, when confined, they will feed on raw meat. They are tamed without much difficulty, but require to be kept warm.

There are some other species of the Jerboa; by far the largest of which is the CAPE JERBOA, a native of the mountainous country to the north of the Cape of Good Hope. Its length from the nose to the tail is fourteen inches, and the tail itself somewhat more. The head is broad, the muzzle sharp, and the upper jaw longer than the lower: the ears are large, the whiskers long and black, and the tail is extremely full of hair. It is an animal of great strength and activity, and will spring to the distance of twenty or thirty feet at once. When eating, it sits up-

right in the manner of a squirrel; and it burrows in the ground, like the smaller kind of Jerboas, with great ease and expedition; having five very strong and long claws on each of its fore feet: those on its hind feet are short, and four in number. [See HELMANTS.]

JERFALCON. [See FALCON.]

JOHN CROW VULTURE. The local name in Jamaica for the Turkey Buzzard. [See TURKEY BUZZARD.]

JOHN DORY. [See DORY.]

JUANOS. A singular genus of Coleoptera belonging to the family *Cetoniidae*, one species of which, described by Mr. W. W. Saunders, is still very rare in collections; this is the *J. Ruckert*; it is of a brilliant green with large yellow marks on the elytra, and the male has long fore legs. It is a native of Northern India.

JUMPING HARE. [See HELMANTS.]

JUNGLE-FOWL. (*Megapodius tumulus*.) Mr. Gould, in his able work on the "Birds of Australia," gives an interesting account of this bird, which in size is about that of a common Fowl, and must not be confounded with the Jungle Cock of India, a very different bird. Its mode of constructing its mound-like nest, and its manner of depositing the eggs, &c., very much resemble those described under *TALPODILLA* [which see]. "The Jungle-fowl," we learn, "is almost exclusively confined to the dense thickets immediately adjacent to the sea-beach: it appears never to go far inland, except along the banks of creeks. It is always met with in pairs or quite solitary, and feeds on the ground, its food consisting of roots which its powerful claws enable it to scratch up with the utmost facility, and also of seeds, berries, and insects, particularly the larger species of Coleoptera. It is at all times a very difficult bird to procure: for although the rustling noise produced by its stiff pinions when flying away be frequently heard, the bird itself is seldom to be seen. Its flight is heavy and unsustained in the extreme; when first disturbed it invariably flies to a tree, and on alighting stretches out its head and neck in a straight line with its body, remaining in this position as stationary and motionless as the branch upon which it is perched: if, however, it becomes fairly alarmed, it takes a horizontal but laborious flight for about a hundred yards, with its legs hanging down as if broken. I did not myself detect any note or cry, but from the natives' description and imitation of it, it much resembles the clucking of the domestic fowl, ending with a scream like that of the peacock." The head and crest of this bird is of a very deep cinnamon brown; back of the neck and all the under surface very dark gray; back and wings cinnamon brown; upper and under tail coverts dark chestnut brown; tail blackish brown; bill reddish brown, with yellow edges; tarsi and feet bright orange. It appears that on Mr. Gilbert's arrival at Port Essington his attention was attracted to numerous great mounds of

earth which were pointed out to him by some of the residents as being the tumuli of the aborigines. The natives, on the other hand, assured him that they were formed by the Jungle-fowl for the purpose of hatching its eggs: and so it afterwards proved. One of these mounds is described as fifteen feet high, and sixty in circumference at the base, and so enveloped in thickly foliaged trees as to preclude the possibility of the sun's rays reaching any part of it.

KAIHAU. The Proboscis Monkey. [See MONKEYS.]

KAKAPO. A New Zealand parrot. [See STRIGOPS.]

KALONG. The name given to several species of Fox-bats (*Pteropida*). [See PTEROPUS.]

KANGAROO. (*Macropus*.) This extraordinary animal is peculiar to Australasia, and belongs to the marsupial order of quadrupeds; but it receives its scientific name from the enormous length of the hind feet, which is the distinguishing characteristic in all the animals included in the family *Macropodidae*, or Kangaroo tribe. But before we proceed to describe the form and habits of this singular quadruped, we shall mention the circumstances (as detailed by Dr. Shaw) attending its first discovery. This was in 1770, when the celebrated navigator Captain Cook was stationed for a short time on that part of the coast of New Holland which is now called New South Wales. On Friday, June 22, says Captain Cook, a party who were engaged in shooting pigeons for the use of the sick of the ship, saw an animal which they described to be as large as a greyhound, of a slender make, and extremely swift. The following day the same kind of animal was again seen by a great many other people. On the 24th it was seen by Captain Cook himself, who, walking at a little distance from the shore, observed a quadruped, which he thought bore some resemblance to a greyhound, and was of a light mouse-colour, with a long tail, and which he should have taken for a kind of wild dog, had not its extraordinary manner of leaping, instead of running, convinced him of the contrary. Mr. Banks also obtained a view of it, and immediately concluded it to be an animal perfectly new and undescribed. Some time after, this gentleman, accompanied by a small party, had an opportunity of chasing two with his greyhound, which the Kangaroo, by its bounding leaps over the high grass, soon outstripped. It was not long, however, before one was shot; and the scientific associates in this expedition of discovery were then fully gratified.

The upper parts of the Kangaroo are small, while the lower are remarkably large in proportion; yet its general appearance is decidedly picturesque. The head bears some resemblance to that of a deer, and the visage is mild and placid: the ears are moderately large, rather pointed, and upright; the eyes large, and the mouth rather small; the neck thin and finely proportioned; the

fore legs extremely short, with the feet divided into five toes, each furnished with a short and somewhat hooked claw; the hinder feet, on the contrary, are provided with only four toes, the middle one of which is long, of great strength, and terminated by a large and powerful hoof-like nail or claw: so that the head and upper parts seem strangely disproportioned to the posterior parts of the animal, which are robust and powerful. The tail, which is very long, is extremely thick at the base, gradually tapering, and appears to act as a supplemental limb, when the animal assumes its erect or sitting posture. When feeding, it is seen in a crouching position, resting on its fore paws, as well as on the hinder extremities, whilst it browses on the herbage; and in this attitude it hops gently along, deriving some assistance from its tail. On the least alarm, however, it raises itself on its hind legs, and bounds away to a distance with great rapidity. The leap is of very great length; and is accomplished by the muscular action of the tail, almost as much as by that of the limbs. They use their tails and hinder feet also as weapons of defence: for when pursued and overtaken by dogs, they turn, and seizing them with their fore feet, strike them with their hinder ones, sometimes causing death by a single blow. The under side of the hind foot has a callous sole along its whole length; and its great length is chiefly given by the elongation of the metatarsal bones. Kangaroos have no canine teeth: their incisors are six in the upper jaw, and but two in the lower; the former short, and the latter long; the molars, which are separated from the incisors by a large vacant space, are ten in number in each jaw. They are exclusively herbivorous in their diet, feeding chiefly on grass: and they associate in small herds, under the guidance of the older males. The ventral pouch, or receptacle for the young, with which the female Kangaroo is furnished, is indeed a most curious provision of nature. Being situated just below her breasts, there the young ones sit to suck; and even when they are old enough to leave the pouch, for exercise or amusement, they immediately seek refuge in it on the least alarm.

The number of species which are now known are very considerable: they vary in size, from that of a rat to the Great Kangaroo, the male of which has been known to measure nearly eight feet from the nose to the tip of the tail, and to weigh 220 lbs.; but in form and habits they bear a strong resemblance to each other. The young are produced in an extremely imperfect state, and are even disproportionately small; not exceeding an inch in length. These animals are easily tamed; and when in a state of domestication, they are harmless and timid. Their flesh is eaten in Australia, and is said to be nutritious. Some persons are loud in their commendations of it; Colonel Light, indeed, goes so far as to recommend all who are fond of ox-tail soup (and they are not a few), to take a trip to South Australia, and eat Kangaroo-tail

soup; which, he says, if made with the skill that soups in England are, would as far surpass the ox or turtle does the French *potage*.

Mr. Gould's great work on the Kangaroo Family is a most noble contribution to Natural History; in it all the species are figured and described with the hand of a master. We must also refer to the work of Mr. Waterhouse, who has devoted a thick octavo volume to their history. Both these works are indispensable to those who would desire to study this important family.

KERMES. (*Coccus ilicis*.) An insect produced in the excrecences of a small oak, the *Quercus coccifera*, and found in many parts of Asia and the South of Europe. The body of this insect is full of reddish juice, and when dead, and transformed into an apparent grain or berry, it is used for the purpose of dyeing a brilliant red colour. They were long taken for the seeds of the tree on which they live, and hence called *grains of Kermes*. Kermes is now nearly superseded by the use of cochineal, but though much inferior in brilliancy to the scarlet cloths dyed with real Mexican cochineal, they retain the colour better, and are less liable to stain. This is said to have been the celebrated Phœnician dye. [See COCHINEAL.]

KESTREL. (*Falco Tinnunculus*.) A beautiful bird of the Hawk kind, known also as the Stannel Hawk, and Windhover. The male is about fourteen inches in length, and in breadth two feet three inches. Its colours, at first sight, distinguish it from all other hawks: the crown of the head, and the greater part of the tail, are of a fine light gray hue; and on the lower part of the latter there is a broad black bar, succeeded by white tips. The back and coverts of the wings bright cinnamon brown, spotted with black; quill feathers dusky, with light edges; inside of the wings white, beautifully spotted with brown on the under coverts, and barred on all the quills with pale ash. The whole under side of the bird is of a pale rust colour, streaked and spotted with black. The bill blue; cere and eyelids yellow; legs yellow; claws black. The colours of the female are less vivid than those of the male: the back and wing-coverts are rusty brown, and elegantly marked with numerous undulated bars of black; the breast, belly, and thighs are of a pale reddish buff, with dusky streaks pointing downwards; and the tail is marked by a pretty broad dark ash-coloured bar near the end.

The Kestrel is widely diffused throughout Europe, and is by no means rare in the more temperate parts of North America. It breeds in the hollows of decayed trees, and in the holes of rocks, towers, and ruined buildings; and lays four or five pale reddish eggs. It feeds on small birds, field mice, reptiles, and insects; after securing its prey, it plucks the feathers very dexterously from birds, but swallows mice entire, and discharges the hair, in the form of round balls, from its mouth. This bird, when in quest of food, "glides softly through the air, at a mode-

rate height, now poised in the breeze on fluttering pinion, now resting in the void apparently without motion; till, at last, down he comes, like a falling stone, upon the unconscious prey below." That discerning friend of the feathered tribes, Mr. Waterton, whose words we have just quoted, thus apostrophizes in this bird's favour: "Did the nurseryman, the farmer, and the country gentleman, know the value of the Windhover's services, they would vie with each other in offering him a safe retreat. He may be said to live almost entirely on mice; and mice, you know, are not the friends of man; for they bring desolation to the bee-hive, destruction to the pen-bed, and spoliation to the corn-stack. Add to this, they are extremely injurious to the planter of trees." Again, "I prize the services of the Windhover Hawk, which are manifest by the quantity of mice he destroys; and I do all in my power to put this pretty bird on a good footing with the gamekeepers and sportsmen of our neighbourhood. Were this bird properly protected, it would repay our kindness with interest; and we should then have the Windhover by day, and the owls by night, to thin the swarms of mice which overrun the land." "The Windhover," he further observes, "is a social bird, and, unlike most other hawks, it seems fond of taking up its abode near the haunts of men. What heartfelt pleasure I often experience in watching the evolutions of this handsome little falcon! and with what content I see the crow and the magpie forming their own nests; as I know that, on the return of another spring, these very nests will afford shelter to the Windhover! Were I to allow the crow and the magpie to be persecuted, there would be no chance for the Windhover to rear its progeny here; for Nature has not taught this bird the art of making its nest in a tree. How astonishing, and how diversified, are the habits of birds! The Windhover is never known to make use of a nest until it has been abandoned for good and all by the rightful owner; whilst, on the contrary, the cuckoo lays her egg in one of which the original framer still retains possession."

KIANG. [See SUPPLEMENT.]

KING-BIRD. [See TYRANT FLYCATCHER.]

KING-FISH. [See OPAH.]

KINGFISHER. (*Alcedo*.) A rather numerous genus of birds, and widely diffused in warm climates, although there is but one species occurring in Europe. They are, in general, birds of an inelegant shape, the head being large in proportion to the size of the body, and the legs and feet very small; but they are of singular brilliancy of plumage, in which blue, green, and orange are the prevailing colours. They are distinguished by having a long, straight, strong, and acute bill; wings rather short; body thick and compact; head large and elongated; plumage thick and glossy. In some of the larger species, however, the colours are more obscure, exhibiting a mixture of brown, black,

and white, variously modified in the different birds. In their manners they all seem to agree; frequenting the banks of rivers, &c., where, perched on a branch of a tree, or other projecting object, they will remain motionless for hours, watching till some fish comes under its station, when the bird dives perpendicularly down into the water, and brings up its prey with its feet, carries it to land, kills it by repeated strokes of the bill, and immediately swallows it: afterwards casting up the scales and other indigestible parts, in pellets, like birds of prey.

THE COMMON OR EUROPEAN KINGFISHER. (*Alcedo ispida*.) This retired and solitary bird, which is only to be found near rivers, brooks, or stagnant waters, subsisting entirely on the smaller kinds of fish, is only seven inches in length, and eleven in breadth: its bill is nearly two inches long, the upper mandible being black, and rather red at the base; the under one, as well as the inside of the mouth, orange-coloured: the throat is white: the crown of the head is a deep shining green, with numerous transverse bright blue streaks: the shoulders and whole wings dark green, but the edges of the gull feathers are glossed with pale blue, and the shoulders marked by numerous small blue spots. The middle of the back, the rump, and coverts of the tail are of a most resplendent azure: the tail is very short, and of a deep rich blue colour; and the whole under part of the body is of a bright orange: legs red; claws black. The female commonly deposits her eggs (which are from five to eight in number, and perfectly white) in a hole in the river's banks, which has probably been made by the mole or the water-rat. If the nest be robbed, the bird returns and lays in the same situation. "I have had," says Reaumur, "one of these females brought me, taken from her nest about three leagues from my house. After admiring the beauty of her colours, I permitted her to fly; when the fond creature was instantly seen to repair to the nest where she had just before been made a captive: there joining the male, she again began to lay, though it was for the third time, and the season was very far advanced. At each time she had seven eggs." In this country the Kingfisher begins to lay early in the season, and excludes her first brood about the beginning of April. The fidelity of the male exceeds that of the turtle: he brings the female large supplies of fish during the season of incubation; and she, contrary to most other birds, is always plump and fat at that time. The male, when on other occasions always makes a twittering noise, now enters the nest with all the silence and circumspection imaginable. The young are hatched at the expiration of twenty days; but they do not acquire the beauty of their plumage till after the first moulting season. This bird is usually seen flying rapidly near the surface of the stream; and the velocity with which it maintains its flight, considering the shortness of its wings, is really surprising.

The ancients attributed to the Kingfisher innumerable habits and properties equally

Improbable. They supposed that it built its nest upon the ocean; but as this floating cradle would be likely to be destroyed by storms, they endowed the bird with powers to lull the raging of the waves during the period of incubation: hence those tranquil days near the solstice were termed *halcyon* days; and that the feathered voyager might want no accomplishment, they attributed to it the charm of song. They also kept the dead body of the bird as a safeguard against thunder, and as a relic by which the peace of families would be preserved. But it is not to the fanciful genius of the ancients alone that this bird is indebted for wonderful attributes. The Tartars and Ostiaks preserve the skin about their persons as an amulet against every ill; and they consider that the feathers have magic influence, when properly used, in securing a female's love: nor are such superstitions entirely confined to barbarous nations; for there are persons, it is said, who believe that if the body of a Kingfisher be suspended by a thread, its breast, by some magnetic influence, will invariably turn to the north.

We shall now endeavour to point out, in the briefest manner possible, some of the other most important species.—THE GIANT KINGFISHER. (*Dacelo gigantea*.) This is the largest species known, measuring eighteen inches from the tip of the bill to the end of the tail: the colour of the plumage chiefly composed of olive-brown and a pale blue-green. Native of Australia.—PIED KINGFISHER. (*Alcedo rudis*.) Size of the song-thrush. The plumage chiefly party-coloured of black and white. Native of various parts of Asia and Africa.—SMYRNA KINGFISHER. (*Alcedo smyrnensis*.) Size of the missel-thrush. A most brilliantly coloured bird; the bright blue of the wings yielding in lustre to none of the feathered tribes. Native of the hotter parts of both Africa and Asia.—SACRED KINGFISHER. (*Alcedo sacra*.) Crown of the head and upper parts blue-green; the throat white; the under parts pale ferruginous, passing upwards like a collar round the neck. Native of the South Sea Islands.—CRESTED KINGFISHER. (*Alcedo cristata*.) A singularly brilliant and elegant species. The crown of the head covered with long blue-green feathers, barred with black, form a crest; the back, wings, and tail are of an exceeding fine ultramarine blue; the breast, belly, thighs, and covert-feathers under the tail are of a bright orange-colour; and the legs scarlet. Native of Madagascar. The next species demands a more lengthened notice.

THE AMERICAN OR BELTED KINGFISHER. (*Alcedo alcyon*.) This species is distinguished by being of a bluish slate-colour, with a ferruginous band on the breast; having a large collar of pure white round the neck; and an elevated crest on the head: legs extremely short. It inhabits all parts of the North American continent, and is the only species of its tribe found within the United States. "Like the love-lorn swains, of whom poets tell us," says Wilson, "he delights in murmuring streams and falling waters; not, however, merely that they may soothe his

ear, but for a gratification somewhat more substantial. Amidst the roar of the cataract, or over the foam of a torrent, he sits perched upon an overhanging bough, glancing his piercing eye in every direction below for his

BELTED KINGFISHER.—(ALCEDO ALCYON.)

scaly prey, which, with a sudden circular plunge, he sweeps from their native element, and swallows in an instant. His voice, which is not unlike the twirling of a watchmah's rattle, is naturally loud, harsh, and sudden; but is softened by the sound of the brawling streams and cascades among which he generally rambles. He courses along the windings of the brook or river, at a small height above the surface, sometimes suspending himself by the rapid action of his wings, like certain species of hawks, ready to pounce on the fry below; now and then settling on an old dead overhanging limb to reconnoitre. Mill-dams are particularly visited by this feathered fisher; and the sound of his pipe is as well known to the miller, as the rattling of his own hopper. Rapid streams, with high perpendicular banks, particularly if they be of a hard clayey or sandy nature, are also favourite places of resort for this bird; not only because in such places the small fish are more exposed to view, but because those steep and dry banks are the chosen situations for his nest. Into these he digs with bill and claws horizontally, sometimes to the extent of four or five feet, at the distance of a foot or two from the surface. The few materials he takes in are not always placed at the extremity of the hole, that he and his mate may have room to turn with convenience. The eggs are five, pure white, and the first brood usually comes out about the beginning of June, and sometimes sooner, according to the part of the country where they reside. They are very tenacious of their haunts, breeding for several successive years in the same hole, and do not readily forsake it, even though it be visited."

It is this species that Mr. Gosse, in his "Birds of Jamaica," thus prettily describes:—"Where the mangrove or the sea-grape stretches its branches down to the water's edge, stopping the way along the yellow beach, the Kingfisher delights to resort, sitting on a projecting twig; here he waits patiently for the approach of some small

fish, on which he drops perpendicularly, and having seized it in his powerful beak, emerges from the wave, and returns to his former station to swallow it. It is a very shy and reclusive bird; I have found scarcely any more difficult of approach: the posts of observation which he chooses are mostly such as command a wide view; and it was very wary; long before the gunner can creep within shot, the bird takes alarm, and darts away to a distant tree. Often as it sits watching, and sometimes at the moment of flying, it utters a loud rattling *churr*." "The form of the body of this bird, in conjunction with the head and beak, is wedge-shaped, the tip of the latter being the point. This form is admirably suited for its sudden and impetuous plunges upon its fishy prey; as the powerful texture, great size, sharp point, and cutting edges of the beak, are for holding it. The feathers of the throat and breast are of the closest texture, and lie on each other like scales, preventing the access of any water to the body, while, from their glossy, satiny surface, the water is thrown off instantly on emersion, as from the plumage of a duck. The feet again, though small, are muscular, the tarsus very short, the toes united into a broad, flat palm, and the claws unusually strong, short, and sharp. When one remembers that the Kingfisher digs his own cave out of the clayey or gravelly cliffs to the depth of several feet, we shall see the use of his strong and broad feet, as we may see it also in the Mole."

Mr. Waterton, in his 'Essays,' has furnished some interesting notes on the habits of the Kingfisher, with a selection from which we will conclude the article: "Modern ornithologists," says this gentleman, "have thought fit to remove the Kingfisher from the land birds, and assign it a place amongst the water-fowl. To me the change appears a bad one; and I could wish to see it brought back again to the original situation in which our ancestors had placed it: for there seems to be nothing in its external formation which can warrant this arbitrary transposition. The plumage of the Kingfisher is precisely that of the land bird, and, of course, some parts of the skin are bare of feathers; while the whole body is deprived of that thick coat of down so remarkable in those birds which are classed under the denomination of water-fowl. Its feet are not webbed, its breast-bone is formed like that of land birds; and its legs are ill calculated to enable it to walk into the water. Thus we see that it can neither swim with the duck, nor dive with the merganser, nor wade with the heron. Its act of immersion in the water is quite momentary, and bears no similarity to the immersion of those water-fowl which can pursue their prey under the surface, and persevere for a certain length of time, till they lay hold of it. Still the mode of taking its food is similar to that of the gulls, which first see the fish, and then plunge into the deep to obtain it; but this bird differs from the gull in every other habit." "If the Kingfisher is to be considered a water-bird merely because it draws its sustenance from

the water, then our modern innovators ought to consider the osprey in the same light: and even the barn owl might give them a hint that she feels inclined to seek a new acquaintance; for I myself have seen her plunge into the water, bring out a fish, and convey it to her nest. Indeed, the swallow, with a still better grace, might ask permission to form a new division, distant both from land and water-birds, and call it ethereal; because it procures the whole of its sustenance from insects in the circumambient air." "I love to take my stand behind a large tree, and watch the Kingfisher as he hovers over the water, and at last plunges into it, with a velocity like that of an arrow from a bow. How we are lost in astonishment when we reflect that instinct forces this little bird to seek its sustenance underneath the water; and that it can emerge from it in perfect safety; though it possesses none of the faculties (save that of plunging) which have been so liberally granted to most other birds which frequent the deep! I sometimes fancy that it is all over with it, when I see it plunge into a pond, which I know to be well stocked with ravenous pike; still it invariably returns uninjured, and prepares to take another dip." "There are people who imagine that the brilliancy of the plumage of birds has some connection with a tropical sun. Here, however, in our own native bird, we have an instance that the glowing sun of the tropics is not required to produce a splendid plumage. The hottest parts of Asia and of Africa do not present us with an azure more rich and lovely than that which adorns the back of this charming little bird; while throughout the whole of America, from Hudson's Bay to Tierra del Fuego, there has not been discovered a Kingfisher with colours half so rich or beautiful. Asia, Africa, and America offer to the naturalist a vast abundance of different species of the Kingfisher. Europe presents only one; but that one is like a gem of the finest lustre."

KINKAJOU. (*Cercopithecus*.) A genus of Plantigrade Carnivora allied to the Coati-mondis. It has a very long tail, which is prehensile at the end: the muzzle is short, the

KINKAJOU. — (*CERCOPI THECUS CAUDIVOLUTUS*.)

tongue slender and extensible; with two pointed molars before, and three tubercular ones behind. One species only is known, (*Cercopithecus caudivolutus*.) [See PORRO.]

KITE. (*Falco milvus*.) This well-known bird may be distinguished from all the rest of the hawk kind by its forked tail. Its length is a little more than two feet, and its breadth five: the bill is two inches long, very much curved at the end, and of horn

colour: the feathers on the head and neck are long and narrow, of a hoary colour, streaked with brown; legs yellow; claws black. It is almost perpetually on the wing; and appears to repose on the bosom of the air without making the least effort to support itself, so easy and elegant is its

KITE. (FALCO MILTUS.)

motion there. It is, however, intent on its prey beneath: and as the young chicken, ducks, goslings, &c. suffer by the Kite's depredations, it is proscribed by the universal voice of every rural district. Were it not for this, its appearance would be welcomed as the harbinger of clear skies and fine weather; for it is in such that it makes its principal excursions. It breeds in large forests, or wooded hilly countries, and lays two or three eggs, of a whitish colour, spotted with pale yellow, and of a roundish form. In the breeding season it will at times approach near the outskirts of villages, seeking materials for its nest; but in general it avoids the haunts of man. The nest is usually in the fork of a thick tree, where it is concealed by the branches: the external part is formed of twigs, thickly matted together; and the interior is lined with wool, or some other soft and warm substance. The young remain a long time in the nest, and are extremely voracious in their appetite; so that to provide them with food requires considerable labour, and greatly heightens the parent bird's audacity.

There was a time when the Kite appears to have been of as much service in London, as the Vulture still is in some of the crowded cities of the East; for we read that in the reign of Henry VIII. the British metropolis swarmed with Kites, attracted thither by the various kinds of offal thrown into the streets, and that these birds fearlessly ascended, and fearlessly performed the scavenger's office in the midst of the people, it being forbidden to kill them. When such a fact as this is brought before our eyes, the "street nuisances" of the present day appear like a comparative luxury; and we are apt to think that "metropolitan improvements" must have since gone on at such a rate that there can no longer be any room for them.

THE MISSISSIPPI KITE. (*Elanus Mississippiensis*.) The celebrated American ornithologist, Wilson, thus introduces this species: "In my perambulations I frequently remarked this hawk sailing about in easy circles, and at a considerable height in the air, generally in company with the turkey buzzards, whose manner of flight it so exactly imitates as to seem the same species, only in miniature, or seen at a more immense height. Why these two birds, whose food and manners, in other respects, are so different, should so frequently associate together in air, I am at a loss to comprehend. We cannot for a moment suppose them mutually deceived by the similarity of each other's flight: the keenness of their vision forbids all suspicion of this kind. They may perhaps be engaged, at such times, in mere amusement, as they are observed to soar to great heights previous to a storm; or, what is more probable, they may both be in pursuit of their respective food. One, that he may reconnoitre a vast extent of surface below, and trace the tainted atmosphere to his favourite carrion; the other, in search of those large beetles, or coleopterous insects, that are known often to wing the higher regions of the air; and which, in the three individuals of this species of hawk which I examined by dissection, were the only substances found in their stomachs. For several miles, as I passed near Bayo Manchak, the trees were swarming with a kind of cicada, or locust, that made a deafening noise; and here I observed numbers of the hawk now before us sweeping about among the trees like swallows, evidently in pursuit of these locusts; so that insects, it would appear, are the principal food of this species. Yet when we contemplate the beak and talons of this bird, both so sharp and powerful, it is difficult to believe that they were not intended by nature for some more formidable prey than beetles, locusts, or grasshoppers; and I doubt not but mice, lizards, snakes, and small birds, furnish him with an occasional repast.

"This hawk, which proved to be a male, though wounded and precipitated from a vast height, exhibited, in his distress, symptoms of great strength, and an almost unconquerable spirit. I no sooner approached to pick him up than he instantly gave battle, striking rapidly with his claws, wheeling round and round as he lay partly on his rump; and defending himself with great vigilance and dexterity; while his dark red eye sparkled with rage. Notwithstanding all my caution in seizing him to carry him home, he struck his hind claw into my hand with such force as to penetrate into the bone. The Mississippi Kite measures fourteen inches in length, and three feet in extent. The head and neck of a hoary white; the lower parts a whitish ash; bill, cere, lores, and narrow line round the eye, black; back, rump, scapulars, and wing-coverts, dark blackish ash; wings very long and pointed; the primaries are black, marked down each side of the shaft with reddish sorrel: all the upper plumage at the roots is white; the scapulars are also spotted with white; tail

slightly forked, and, as well as the rump, jet black : legs vermillion, tinged with orange, and becoming blackish towards the toes ; claws black ; iris of the eye dark red ; pupil, black. The long pointed wings and forked tail point out the affinity of this bird to that family or subdivision of the *falco* genus, distinguished by the name of Kites, which sail without flapping the wings, and cut from their talons as they glide along."

KITTEN [MOTHS]. A name given by collectors to Moths of the genus *Cerura*.

KIWI. A remarkable and curious bird of New Zealand, which we have described under **APTERYX**, (*Apteryx Australis*) or Wingless Emu. "These birds," the Rev. W. Yate observes, "hide themselves during the day; and come out of their retreats, which are generally small holes in the earth, or under stones, at night, to seek for their food. They run very fast, and are only to be caught by dogs, by torch-light, which they sometimes kick and bruise severely. They are highly prized, when taken, which is very rarely, by the natives; and their skins are kept till a sufficient number are collected to make into a garment. I have only seen one garment made of skins of this bird, during my six years and a half residence in New Zealand: and no consideration would induce the man to whom it belonged to part with it." The flesh is black, sinewy, tough, and tasteless. [See **APTERYX**.]

KNOTHORN [MOTHS]. A name given by collectors to Moths of the genus *Phycita*.

KOKAKO. The name given by the natives of New Zealand to a corvine bird, called, by some, the New Zealand Crow. [See **GLAUCOPIS CINEREA**.]

KOODOO, or STRIPED ANTELOPE. (*Antelope strepsiceros*.) This magnificent animal has no rival among the Antelope genus for beauty and height, or for bold and widely-spreading horns. It is eight feet in length

and four feet in height at the shoulder; with ponderous horns beautifully twisted, having a prominent spiral ridge running obliquely from the base to the point, and extending to the length of about four feet. The colour of the back and sides is a light brown, with a narrow white band along the spine, and several similar stripes descending obliquely down the sides and hips; the belly and under parts being of a pale hue. The head is large, the ears broad, and the limbs thick and robust; yet, notwithstanding its heavy make, it takes long bounding leaps with surprising agility. It inhabits the woody parts of Caffraria, along the banks of the rivers; and when pursued takes to the water.

KUKUPA. A beautiful species of Wood-pigeon known by this name in New Zealand, where it is very plentiful. It is described by the Rev. W. Yate as "much larger than the largest wild or tame pigeons in England, and has a plumage unrivalled among the extensive family of doves for splendour and variety: green, purple, and gold are, however, the prevailing colours. It is a heavy-flying bird, which makes it an easy prey to the hawks, with which the woods abound. They are easily killed with a spear or a musket; and if two birds are found upon the same tree, they are either so sluggish or stupid as not to fly when one is either killed, or wounded. They feed upon the berries of the *Miro*; are most delicious eating; and are in season from January to June. The natives destroy vast numbers of these birds, and value them much, on account of both the quantity and the quality of their flesh.

LABRUS: LABRIDÆ. A genus and family of Acanthopterygious fishes, the species of which are very numerous in tropical seas; and even on our own shores they are abundant. The *Labridæ* family (Wrasses or Rock-fish, as they are also called) are chiefly remarkable for their thick fleshy lips, their large and strong conical teeth, their oblong scaly body, and their brilliant colours. They are further generically distinguished by a single dorsal fin, extending nearly the whole length of the back. [See **WRASSE**.]

LABYRINTHODON. [See **SUPPLEMENT**.]

LACERTA: LACERTIDÆ. A genus and family of reptiles. [See **LIZARD**.]

LACKEY [MOTHS]. A name given by collectors to species of Moths of the genus *Climacampa*.

LADY-BIRD. The popular name given to a well-known genus of coleopterous in-

KOODOO, OR STRIPED ANTELOPE.
(*ANTILOPE STREPSICEROS*.)

LADY-BIRD AND LARVA.

sects, which are sometimes seen, in vast numbers, in hop plantations, &c., where they are of infinite service in destroying the various species of *Aphides*, which are so prejudicial to certain plants and fruit-trees. [See COCCINELLA.]

LÆMODIPODA. The name of an order of marine Crustaceans, with sessile eyes, and in which the posterior extremity of the body exhibits no distinct branchiæ. The body is almost linear or filiform, and with the head consists of eight or nine segments, with some small tubercle-like appendages at its posterior and inferior extremity: the limbs are terminated by a strong hook. The females carry their ova beneath the second and third segments of the body in a pouch formed of approximated scales. The *Cyamus Ceti*, or Whale louse, is an example of this order.

LAGOMYS. A genus of Rodent Quadrupeds, separated from the Hares. The **ALPINE LAGOMYS** (*Lagomys Alpinus*) has sometimes been confounded with the Varying Hare, in consequence of the latter having also obtained the name of *Alpine*; but is a far smaller animal, scarce exceeding a Guinea-plg (*Caria copayba*) in size, and measuring only nine laches in length; while it has a long head, and the ears are short, broad, and rounded. It is a native of the Altaic mountains, extending even as far as Kamtschatka; inhabiting woody tracts amidst rocks and cataracts, and forming burrows beneath the rocks, or lodging in their fissures. In fair weather they seldom leave their holes in the day-time; but when the weather is dull they are seen running about among the rocks, and frequently uttering a sort of whistle or chirping bird-like sound. During the autumn they prepare for their winter support, by collecting a plentiful assortment of the finest herbs and grasses; which, after drying in the sun, they dispose into heaps of various sizes, according to the number of animals employed in forming them: these are easily distinguishable even through the deep snow, being often several feet in height and breadth. These little hayricks, raised by their industrious labours, are often found of great service to the adventurous sable-hunters, whose horses would perish were it not for the supplies which they thus occasionally discover. For this reason the Alpine Hare has a name among every Siberian and Tartar nation where it is found: a circumstance which marks its importance to society: for few animals, so diminutive, are noticed in those regions, unless possessed of some valuable or attractive qualities.

THE OGOTONA HARE. (*Lagomys Ogotona*.) This little animal, whose length is only six inches, inhabits the vast deserts of Mongolia, and the frontiers of Chinese Tartary, living in sandy plains or on rocky mountains. It sometimes burrows under the soil, or conceals itself under heaps of stones, and forms a soft nest at no great depth from the surface. Before the approach of winter these animals collect large quantities of herbs, with which they fill their holes; and di-

rected by the same instinct as the Alpine Lagomys, they also form hemispherical ricks of hay, about a foot high, for their support during the inclement season. The colour of the Ogotona Hare is a pale brown above, and white beneath: on the nose is a yellowish spot, which colour is seen on the out-sides of the limbs and the space about the rump. Hawks, magpies, and owls indiscriminately prey on them; but their most formidable enemies are the cat, the fitchet, and the ermine.

THE CALLINO HARE (*Lagomys pusillus*) extremely resembles the Ogotona Hare, just described, but is rather smaller. The head is long, and covered with fur to the very tip of the nose; the ears are large and rounded; and the legs very short. The whole body is covered with very soft, long, smooth fur, of a brownish lead colour, with the hairs tipped with black; but on the sides a yellowish tinge prevails. It is an inhabitant of the south-east parts of Russia, and is an animal of so solitary a nature, that it is very rarely to be seen even in places it most frequents. It commonly chooses its residence

CALLINO HARE. — (*LAGOMYS PUSILLUS*.)

in some dry gentle declivity, where the turf is firm and covered with bushes; it there forms an obliquely descending burrow, the entrance of which is scarcely more than two inches in diameter; and so numerous and intricate are the avenues which lead to their retreats, that they would with great difficulty be discovered, did not their voice betray them. This voice resembles the piping of a quail, but is so loud that it may be heard at a surprising distance, particularly as there is nothing in the structure of its organs which can account for so powerful a tone. These little animals are of an extremely gentle disposition, and easily tamed. Their pace is a kind of leaping motion, but not very quick, nor do they run well, on account of the shortness of their legs.

LAGOPUS. [Sec PTARMIGAN.]

LAGOSTOMUS. A genus of Rodent Mammalia, in which the fore feet are furnished with four toes, the hinder with three only, as in the Canies, all of them armed with stout claws adapted for digging. The ears are of moderate size, and the tail comparatively short. Their three anterior molars of the upper jaw consist each of two double layers, and the last of three. The only known species (*Lagostomus trichodactylus*) is about the size of a Hare, and inhabits Chili and Brazil: its general colour

Is grayish; the fur of two sorts, one entirely white, and the other, which is coarser, black, except at the base; the under parts white. Its motions are quick, and resemble those of a Rabbit; and it seeks its food by night,

LOOSTOMUS VISCACHA.

subsisting wholly on vegetables; inhabits the level country; and is not esteemed as food. It has very generally obtained the name of *Viscacha*; and it has also been figured in Griffith's edition of Cuvier's *Regne Animal* under the name of the *Diana Marmot*.

LAGRIIDÆ. A family of small Coleopterous insects, found in woods and hedges, and upon plants, counterfeiting death when alarmed, like the *Cantharida*. The head and thorax are narrow; the elytra soft and flexible; and the antennæ filiform. Their bodies are soft, and although they creep but awkwardly, they are active on the wing. The larvae are found in the winter, under dead oak leaves, upon which they feed; when disturbed, they roll themselves up, with the head bent towards the tail; and they assume the pupa state without forming any cocoon. The species are few in number, but widely dispersed.

LAMB. The young of the SHEEP.

LAMBRUS. A genus of short-tailed Crustacea, most of the species of which are tropical: many of them have very long fore-legs, and are curiously covered with knobs and spines.

The *Eurygnom aspera* is the only member of this group found in the British seas.

LAMELLIBRANCHIATA. An order of acephalous (headless) molluscs, in bivalve shells; all the species being aquatic. In these the mouth is not situated upon a prominent part of the body, nor assisted in its choice of food by organs of special sensation in its neighbourhood; but the entrance to the stomach is buried between the folds of the mantle. The shell of these animals is composed of particles of carbonate of lime, exuded from the surface of the mantle, and contained in the cavities of cells, or between layers of membrane; and a constant relation is preserved between the size of the animal and that of its shell. The valves are connected together in various ways. In the first place, they are jointed by a hinge; which is sometimes formed by the locking of a continuous ridge on one valve into a groove in the other, and sometimes by little projections which fit into corresponding hollows in the opposite valve. Near the hinge is fixed the

ligament; which is composed of an elastic animal substance, and answers the purpose of binding the valves together, and at the same time keeping them a little apart, which may be regarded as their natural position. The Lamellibranchiata have usually more power of motion than the other *Acephala*; but they do not in general attain any great size. They are distributed over the whole globe, principally frequenting the shores or shallows; but the largest kinds are only found in warm latitudes.

LAMELLICORNES. The name by which an extensive section of Coleoptera tribe is distinguished. With respect to the size of the body, and the variety of forms exhibited in the head and thorax, it is one of the most beautiful of the coleopterous order; while those species which in their perfect state live upon fresh vegetable substances display metallic colours of great brilliancy: the majority, however, are of an uniform black or brown colour. All have wings; and they crawl but slowly on the ground. They feed on manure and other decomposed substances; but some species subsist on the roots of vegetables, and in their larva state do great injury to the cultivator. The antennæ are always short; they usually consist of nine or ten joints, and are terminated in a club, generally composed of the three last, which are lamellar, and are either arranged like a fan, a comb, or the leaves of a book. The larvae have the body long, nearly semi-cylindrical, soft, often transversely wrinkled, whitish-coloured, twelve-jointed, with the head scaly, armed with strong jaws and six scaly feet. A general idea of their form may be obtained from that of the grub which produces the common Cockchafer. Some species do not change to pupæ until they have passed three or four years as larvae; they form for themselves in their retreats, with the earth or the debris of the materials they have gnawed, a cocoon of an unvoid form, or in the shape of an elongated ball, of which the particles are fastened together with a glutinous secretion.

LAMELLIPEDES. The term applied to the third section of the order *Conchifera* *Dinmyaria*, containing Bivalves, with the foot of the animal broad and thin; as in the genus *Cardium*, &c.

LAMPREY. (*Petromyzon marinus*.) This fish has a long and slender body, nearly cylindrical, resembling an eel; and its skin, which has no scales, is covered with a glutinous mucus. The Marine or Sea Lamprey sometimes grows to a very large size (three feet in length); the British specimens, however, are generally far inferior in magnitude. The usual colour of the Lamprey is a dull brownish olive, clouded with yellowish-white variegations; the back darker than the other parts, and the abdomen paler; the fins are tinged with dull orange, and the tail with blue. The mouth is of a round form, resembling that of a leech, and, like it, possesses the power of sucking and adhering to stones or other substances with extraordinary tenacity. The tongue, which moves

to and fro like a piston, and which is the principal instrument in the act of suction, is furnished with two longitudinal rows of small teeth, and the mouth is lined with several circular rows. On the top of the head is a small orifice or spout-hole, through which is discharged the superfluous water taken in at the mouth and gills; and on each side the neck is a row of seven equidistant spiracles, or breathing-holes. In reference to this respiratory apparatus Mr. Owen has remarked, that "when the Lamprey is firmly attached, as is commonly the case, to foreign bodies, by means of its snorial mouth, it is obvious that no water can pass by that aperture from the pharynx to the gills; it is therefore alternately received and expelled by the external apertures." The first dorsal fin, which is rather shallow, with a rounded outline, commences towards the lower part of the back; the second is nearly of the same extent, but with a sub-triangular outline: the tail is short, and slightly rounded.

The Lamprey usually quits the sea in the spring for the purpose of spawning, and after an absence of a few months returns to its original marine element. When in motion this fish is observed to swim with considerable vigour and rapidity, but it is more commonly seen attached by the mouth to some large stone or other substance, the body hanging at rest, or obeying the motion of the current, so strong is its power of suction. Its general habits seem pretty much to resemble those of the eel; and, like the eel, it is remarkably tenacious of life. The Lamprey, though its ancient repute no longer remains, is still considered as a delicacy at certain seasons of the year; and the potted Lampreys and Lamperns of Worcester are in high estimation; those taken in the Severn being preferred to all others. During cold weather, this fish conceals itself in the crevices of rocks; and it is a usual expedient with anglers to form pits extending to the water-side in the vicinity of its haunts; into these a little blood is thrown, to induce the Lamprey to come forth, when it is readily taken.

THE RIVER LAMPREY, OR LAMPERN. (*Petromyzon fluviatilis*.) This well-known species inhabits fresh waters, and is common in the Thames, the Severn, the Dee, the Tweed, &c. It is from twelve to fifteen inches in length; has a rounded head, a slender cylindrical body for about two-thirds of its length, and then compressed to the end of

LAMPREY, (*PETROMYZON FLUVIATILIS*.)

the tail. "Formerly," says Mr. Yarrel, "the Lampern was considered a fish of considerable importance. It was taken in great

quantities in the Thames from Battersea Reach to Taplow Mills, and was sold to the Dutch as bait for the Turbot, Cod, and other fisheries. Four hundred thousand have been sold in one season for this purpose, at the rate of forty shillings per thousand. From five pounds to eight pounds a thousand have been given; but a comparative scarcity of late years, and consequent increase in price, has obliged the line fishermen to adopt other substances for bait. Formerly the Thames alone supplied from one million to twelve hundred thousand Lamperns annually. They are very tenacious of life, and the Dutch fishermen managed to keep them alive at sea for many weeks." Great quantities are also taken in the rivers of Germany: after being fried, they are packed in barrels by layers, between each of which is a layer of hay leaves and spices, sprinkled over with vinegar; and in this state they are sent to other countries. This species spawns in April and May. It feeds on insects, worms, &c., and is a prolific fish.—There are a few more species, of a smaller size; but in all the main characteristics they correspond with the foregoing.

LAMPYRIDÆ. A family of Coleopterous insects, having for its type the genus *Lampyrus*. The *Lampyridae* are distinguished by having five joints to all the tarsi; flexible elytra; and the body usually elongated and somewhat depressed; by the thorax projecting more or less over the head; small mandibles, terminated by a sharp point; the penultimate joint of the tarsi always bilobate; the terminal claws simple; and the antennæ approximated at the base. In some species the females are apterous, and in others furnished only with short elytra. They are voracious in their habits; preying in the larva state upon the bodies of snails, and not upon plants. The species are, for the most part, exotic, and are often ornamented with red or yellow and black colours. Scarcely any exceed an inch in length. When alarmed, they fold their antennæ and legs against the body, and remain motionless, as though dead; many, also, at such times, bend their abdomen downwards. The three most important genera are *Lycus*, *Omolus*, and *Dictyoptera*. [See GLOW-WORMS.]

LANNER. (*Falco lannarius*.) A bird of the long-winged Hawk kind, rather less than the buzzard. It breeds in France, where it continues the whole year, is very docile, and seems well adapted to all the purposes of hawking. It is also met with in Ireland, and is thus described by Pennant: The ear is a palish blue; the crown of the head, brown and yellow clay-colour; above each eye a broad white line passes to the hind part of the head; and beneath each a black mark points downwards. The throat is white; the breast is tinged with dull yellow, and marked with brown spots pointing downwards; the thighs and vent are spotted in a similar manner; the back and coverts of the wings are a deep brown, edged with a paler tinge; the quill-feathers are dusky; the inner webs are marked with

oval rust-coloured spots; and the tail is spotted in the same manner as the wings.

LANTERN-FLY. (*Fulgora lanternaria*.) This insect is curious both on account of its size and its singular properties. It is nearly three inches and a half in length from the tip of the front to that of the tail, and about five inches and a half broad with its wings expanded: the body is of a lengthened oval shape, sub-cylindric, and divided into several rings or segments; while the head is distinguished by a singular prolongation, which sometimes equals the rest of the body in size. In this projection the luminous property of the Lantern-fly is said to exist; but the luminosity of this insect—of which there are several species—is doubted by most naturalists; who say, that if it really exists, it is only at particular seasons. It is therefore but right that we should give our authority:—Madame Merian, in her work on the Insects of Surinam, says, "The Indians once brought me, before I knew that they shone by night, a number of these Lantern-flies, which I shut up in a large wooden box. In the night they made such

LANTERN-FLY.—(*FULGORA LANTERNARIA*.)

a noise that I awoke in a fright, and ordered a light to be brought; not knowing from whence the noise proceeded. As soon as we found that it came from the box, we opened it; but were still much more alarmed, and let it fall to the ground in a fright, at seeing a flame of fire come out of it; and as many animals as came out, so many flames of fire appeared. When we found this to be the case, we recovered from our fright, and again collected the insects, highly admiring their splendid appearance."

The ground-colour is an elegant yellow, with a strong tinge of green, and marked with numerous bright brown stripes and spots: the wings are very large, and the lower pair are decorated with a large eye-shaped spot on the middle of each, the iris or border of the spot being red, and the centre half red and half semitransparent white; the head or lantern is pale yellow, with longitudinal red stripes. This beautiful insect is a native of several parts of South America. [See *FULGORA*.]

The *Fulgora candelaria*, a native of China, is a much smaller species; measuring about two inches in length, and two inches and a half in breadth. The body is oval, and the head produced into a long horn-shaped process: the colours are very elegant; the head and horn being of a fine reddish

brown, and covered with numerous white specks: the thorax is of a deep yellow, and the body black above, but deep yellow beneath: the wings are oval; the upper pair blackish, with numerous green reticulations, dividing the whole surface into innumerable squares, and farther decorated by several yellow spots: the under wings are orange-coloured, with broad black tips.

LAP-DOG. The little pets of the drawing-room and boudoir who bear the enviable appellation of Ladies' Lap-dogs, and who for years past have been growing "small by degrees and beautifully less," belong to that race of Dogs which have been described as "timid, fond, and affectionate—the most grateful for kindness, the most patient under ill-treatment;"—of course we mean the SPANIELS; and, therefore, under that word will the Lap-dog's zoological character be found. Nature originally, without doubt, had some hand in the production of these highly-favoured diminutives; but her empire over them has long been usurped by Fancy and Fashion, who have agreed—that the ears of these companions of female loveliness should be remarkably long and full, and the hair (of the ears more especially) plentiful and beautifully waved; that "liver-colour-and-white," though its pretensions to beauty are but moderate, is not to be despised; that "black-and-white" is entitled to our particular regard; but that the dear little "black-and-tan" variety is vastly to be preferred to either; while it is absolute treason to honour any with the title of "King Charles's breed" which do not possess certain indubitable signs of royal descent, as a black-roofed mouth, &c. There is also a variety of the Spaniel, generally of a white colour, and the hair of which is extremely long: it is called the Maltese dog, and is said to be one of the most elegant of the Lap-dog tribe.

LAPPET (MOTH). A name given by collectors to species of Moths, of the genera *Gastr. pacha* and *Eutricha*.

LAPWING or PEEWIT. (*Vanellus cristatus*.) This bird, which is about the size of a pigeon, belongs to the snipe and plover tribe. It is found in this country in large flocks, except during the pairing season, when it separates for the purposes of incubation. It builds a slight artificial nest on the ground, and lays four eggs of an olive cast spotted with black. The Lapwing's bill is black; the crown of the head and the crest are of a shining black; the cheeks and sides of the neck, white; the throat and forepart of the neck are black; the hind part, a mixture of red, white, and cinereous. The back and scapulars are of a glossy green colour, the latter variegated with purple: the small wing-coverts are of a resplendent black blue and green hue; the greater quill-feathers are black; and the breast and belly are white. The vent and coverts of the tail are orange-coloured; the tail is black and white; and the legs are red. The young birds run about very soon after they are hatched. During this period the old ones

are very assiduous in their attention to their charge : on the approach of any person, they flutter round his head with great inquietude, and if he persists in advancing they will endeavour to draw him away, by running along the ground as if lame, and thereby inviting pursuit. It subsists chiefly on worms and the animalcula of the sea-shore. These birds are very lively and active during their love season, being almost continually in motion, sporting and frolicking in the air in all directions, or springing and bounding from spot to spot with great agility.

"Far from her nest, the lapwing cries away."—*Shaks.*

In the month of October they are in good condition for the table, and their eggs are considered a delicacy. [See TERUPTER.]

LARIDÆ. Birds of the Gull tribe, all of which are oceanic in their habits, and distinguished for great powers of flight. [See GULL and LESTRIS.]

LARK. (*Alauda*.) There are many species of this bird, and their great characteristic distinction from other birds consists in the extreme elongation in an almost straight line of their hinder claws ; by this formation the prehensile faculty is nearly destroyed, and consequently, with the exception of a few species with shorter claws, they are incapable of perching upon trees. The bill is straight, slender, bending a little towards the end, and sharp-pointed : the toes are all divided to their origin, the nostrils are covered with feathers, and the tongue is bifid. These birds are famed for singing during flight ; and there is something very delightful in listening to their melodious strains when the performers are soaring aloft, beyond the reach of human ken. From the situation of their nests they are greatly exposed to the attacks of predaceous animals of the weasel kind, which destroy great numbers of the eggs and young. The species which first claims our notice is

The **SKY-LARK.** (*Alauda arvensis*.) This delightful songster, the most harmonious of the whole family, is universally diffused throughout Europe, and is everywhere extremely prolific. It is about seven inches in

length : bill dusky, the base of the under mandible yellowish : the feathers on the top of the head are dusky, edged with rufous brown ; they are rather elongated, and may be set up as a crest : the plumage on the upper part of the body is reddish-brown, with the middle darkest, and the edges rather pale : the upper part of the breast is yellow, spotted with black ; and the lower part of the body is a pale yellow. The tail is dusky brown ; legs dusky ; claws dusky ; the hind one being very long, straight, and strong. The male is of a deeper colour, and larger than the female ; and is further distinguished by having the hind claw longer. The species is subject, however, to considerable variety ; and has even been found of a pure white colour. The Sky-lark commences his song early in the spring, continuing it during the whole summer, and is one of the few birds that chant whilst on the wing. When it first rises from the earth, its notes are feeble and interrupted ; as it ascends, however, they gradually swell to their full tone, and long after the bird has reached a height where it is lost to the eye, it still continues to charm the ear with its melody. It mounts almost perpendicularly, and by successive springs, and descends in an oblique direction, unless when threatened with danger, when it drops like a stone. The female forms her nest on the ground, close to some turf, which serves at once to hide and shelter it ; sometimes in corn-fields ; and, at others, in various sorts of pasturage. She lays four or five dirty white eggs, blotched and spotted with brown ; and she generally produces two broods in a year. These prolific birds live on seeds and insects, they are most abundant in the more open and highest cultivated situations abounding in corn, being but seldom seen in extensive moors at a distance from arable land. In winter they assemble in vast flocks, grow very fat, and are taken in great numbers for the table.

The **WOOD-LARK** (*Alauda arborea*) greatly resembles the Sky-lark, though it is much smaller, and the colours are less distinct. The feathers on the crown and upper parts of the body are marked with dusky spots edged with light reddish brown : from the beak over the eye is a narrow yellowish white band surrounding the crown of the head ; the feathers over the ears are brown, beneath which is another light band : quills dusky ; neck and breast yellowish white, tinged with brown, and marked with dusky spots : tail short ; the four outer feathers on each side black, with dirty white tips ; tail-coverts very long and brown : legs yellowish flesh-colour : hind claws long, and slightly bent. It is generally found near the borders of woods, perches on trees, and sings during the night, so as sometimes to be mistaken for the nightingale. When kept in a cage, near one of the latter birds, it often strives to excel it, and, if not speedily removed, will fall a victim to emulation. This species can be easily distinguished from the Sky-lark during flight, as it does not mount in the air in a perpendicular manner, and continue hovering and singing in the same spot like

SKY-LARK.—(*ALAUDA ARVENSIS*.)

that bird; but will often rise to a great height, and keep flying in large irregular circles, singing the whole time with little intermission, sometimes for an hour together.

WOOD-LARK.—(*ALAUDA ARVENSIS*.)

Its song, though not so loud as that of the Sky-lark, is more melodious, and may sometimes be heard in fine weather even in the depth of winter. This bird feeds on grain, seeds, and insects: its nest is placed under a tuft of high grass or furze, or in a low bush; and is made of dry grass, lined with finer grass and hair. The female lays four or five eggs, of a dusky colour, interspersed with deep brown spots, and, like the former species, often raises two broods in the year. It is a general inhabitant of Europe, but not so plentiful as the Sky-lark. It is more abundant in Devonshire than in any other part of England. These birds get very fat after harvest, and are taken in great numbers.

The CRESTED LARK (*Alauda cristata*) is distinguished from other species by the feathers on the crown of the head being much elongated and forming a crest, which is darker than the rest of the plumage. The back is ash-coloured, spotted with brown; the breast and belly yellowish white; and the throat is beautifully spotted. The tail is rather short; the two outer feathers, with their exterior edges, white, tipped with red. The song of this bird is fine, but not equal to the Sky-lark: its aerial excursions are likewise shorter. Though found in many parts of Europe, frequenting the banks of lakes and rivers, it does not appear to be known in England.

The TIT-LARK. (*Anthus pratensis*.) This bird, which by the older writers was classed with the larks, belongs to a different genus and family; but may be described here. It is of an elegant and slender shape, five inches and a half in length, and nine in breadth. The bill is black; the back and head are of a greenish brown colour, spotted with black; the throat and lower part of the belly are white; the breast is yellow, spotted with black; the tail is dusky; and the feet are of a pale yellow colour. In many parts of England this is a very common bird; and is met with in marshes, barren moors, and mountainous heaths: its nest, made of dry grass and stalks of plants, lined with fine grass and horse-hair, is placed on the ground amongst furze and long grass.

The eggs are generally six in number, but vary considerably in size and colour: and the Cuckoo is said to deposit its eggs among them. During the period of incubation, the male pours forth its short but pleasing song: it generally springs into the air, increasing its song as it descends to the ground, from a height of 30 or 40 feet. In winter many Tit-larks betake themselves to the sea-shore.

The TREE TIT-LARK. (*Anthus arborcus*.) This bird greatly resembles the Tit-lark; but may be readily distinguished from it, by the bill being much broader at the base, and the legs being yellowish-brown instead of dusky. It is a solitary species, never associating in flocks, nor seen on the moors and downs, where the Titlark is most abundant. The nest of this species is placed only amongst high grass in the most cultivated parts, where there are plenty of trees. Its eggs, of which there are four, are of a dirty bluish white, blotched and spotted with purplish brown. Its flight is very peculiar, mounting up in a fluttering manner, and after some time descending to a neighbouring tree with motionless wing and expanded tail, and then alighting on the ground, warbling during its descent. It is chiefly found in the western and south-western counties of England.

There are other species enumerated by ornithologists; as the MEADOW LARK, a species common in many parts of Italy; the SHORE LARK, known as an inhabitant both of Europe and America, and very abundant in the latter continent; the BROWN LARK; the ROCK LARK, found at the Cape of Good Hope; the MARSH LARK, native of Germany; the SIBERIAN LARK; the RED LARK; the BLACK LARK, &c.

LARIDÆ. A family of Hymenopterous insects, small in extent, and the species of which it is composed are but of moderate size. They are distinguished by the labrum being entirely or partially concealed, and the mandibles deeply notched on the inner side near the base. They are ordinarily found in sandy situations, and are fossorial in their habits. One species, the beautiful and rare *Dinetus pictus*, is remarkable for the convoluted antennæ of the males; and the exotic genus *Palarus* is not less distinguished by the constricted segments of its abdomen.

LATHAMUS. A genus of Parrakeets found in Australia; as an example we may mention

LATHAMUS DISCOLOR, termed by the colonists of Van Diemen's Land the "Swift Parrakeet." During September and the four following months this migratory species is abundant in the gum forests, and very common in the shrubberies and gardens at Hobart Town; small flocks of them continually flying up and down the streets and over the houses. They gather a fine clear honey from the fresh-blown flowers of the *Eucalypti* (especially *E. gibbosus*), which daily expand. They are quite fearless, and allow the inhabitants to pass within a few feet of their heads. Their eggs are laid in holes in the loftiest and most inaccessible trees. For

other species see Mr. Gould's Birds of Australia.

LEAF-CUTTING BEES. [See MEGACHILE.]

LEECH. (*Hirudo*.) A genus of suctional animals, or red-blooded worms, of aquatic habits, provided with a sucker at both ends of the body: the greater part are inhabitants of fresh water; some, however, are only found in the sea; while others live in moist situations near stagnant water, pursuing earth-worms, &c. Many of them accumulate their eggs into cocoons, enveloped by a fibrous excretion, at first sight so closely resembling sponge in structure as to have been once mistaken by a distinguished naturalist for a new genus of that family. The species which principally deserves our attention is

LEECHES.—(*HIRUDO MEDICINALIS*.)

the common Leech (the *Hirudo medicinalis* of Linnæus). This species, which is usually about the length of the middle finger, bears a considerable resemblance to the earth-worm in its general structure, but differs as to the conformation of its mouth and digestive apparatus. Its skin is composed of from ninety to a hundred or more soft rings, by means of which it acquires its agility, and swims in the water. It has a small head; a black skin, edged with a yellow line on each side, and some yellowish spots on the back; and the belly, which is of a reddish colour, is marked with pale yellow spots. But the most remarkable part is the mouth, which is situated in the middle of the cavity of the anterior sucker; and three little cartilaginous bodies, or jaws, are seen to be disposed around it, in such a manner that the three edges form three radii of a circle. Each of these has two rows of minute teeth at its edge, so that it resembles a

small semicircular saw. It is imbedded at its base in a bed of muscle, by the action of which it is worked, in such a manner as to cut into the skin,—a sawing movement being given to each piece separately. It is in this manner that the tri-radiate form of the leech-bite is occasioned; each ray being a separate little saw, this apparatus enabling the leech to penetrate the skin without causing a dangerous wound. The lacerated character of the wound is very favourable to the flow of blood; which is further promoted by the vacuum created by the action of the sucker. The alimentary canal consists of an œsophagus, a long stomach, with œsophageal sacs, and an intestine. The operation of digestion is extremely slow, notwithstanding the rapid and excessive manner in which the Leech fills its stomach; a single meal of blood will suffice for many months; nay, more than a year will sometimes elapse, before the blood has passed through the alimentary canal in the ordinary manner, during all which period so much of the blood as remains undigested in the stomach continues in a fluid state. This accounts for the reluctance of the Leech, after being used to abstract blood, to repeat the operation; it not only being gorged at the time, but provided with a sufficient supply for so much longer. Indeed, the true medicinal Leech does not seem to take any solid aliment, but subsists on the fluids of frogs, fish, &c. Leeches are furnished with eight or ten simple eyes, which may be detected with a magnifying glass as a semi-circular row of black points, situated above the mouth upon the sucking surface of the oral disc; and to these visual specks it is supposed they are indebted for whatever sight they possess.

Leeches derive their principal interest from the use that is made of them as a remedial agent; but it should be observed that there are only two species so employed, and these are principally derived from the South of France, Sweden, Poland, and Hungary. It is common for the leech-dealers to drive horses and cows into the ponds, that the Leeches may fatten and propagate more abundantly by sucking their blood. Children are also employed to catch them by the hand; and grown persons wade into the shallow waters in the spring of the year, and catch the Leeches that adhere to their naked legs. In summer, when they have retired to deeper waters, a sort of raft is constructed of twigs and rushes, by which a few are entangled. They are also taken by laying baits of liver, to which the Leeches resort, and are then caught; but this last method is thought to make them sickly. A Leech may be known to be in good health if it be active in the water, and plump when taken out. The most certain method of inducing Leeches to bite, is to cleanse the skin thoroughly; and they should be exposed to the air for a short time previous to their application, as by this means they will bite more freely. If they are voracious, they may be applied to the part by being held lightly in the fingers, or they may be placed in a leech-glass, which is a preferable mode.

They should not be disturbed whilst sucking, nor the patient be exposed to too great warmth, or they will fall off; this they should always be permitted to do of their own accord. When the Leech has dropped off, it should be seized by the tail, and drawn between the finger and thumb, so as to cause it to disgorge most of the blood; or this may be effected by putting it in a weak solution of common salt. It should then be placed in many successive fresh waters, and if not injured, it may be used again at a future time.

"The increasing scarcity of Leeches," as is remarked by Mr. Broderip, "renders their preservation and propagation objects of primary importance. The death of a vast number of Leeches is occasioned by errors in the method of keeping them. Though aquatic animals, it is not enough that they be supplied with water. They breathe by their entire surface, and are accustomed to change their skins every four or five days. Their body is covered, like that of all animals and plants which inhabit the water, by a slimy or mucilaginous fluid, which not only enables them to glide through the water, but keeps an aerial stratum in close contact with their respiring surface. When present in a limited degree, this mucous secretion is highly serviceable to them; in excess it is destructive. It is impossible for them to diminish it when it has accumulated, or to denude themselves entirely of their old skin, in water only. They must have some resisting body to creep over or through in order to accomplish this object." The most effectual method of preserving them appears to be that recommended by Fee; which is as follows:—"Into a marble or stone trough a layer of seven laches of a mixture of moss, turf, and charcoal of wood is to be put, and some small pebbles placed above it; at one extremity of the trough, and midway between the bottom and the top, place a thin plate of marble pierced with numerous small holes, upon which there should rest a stratum of moss, or portions of the equisetum palustre, or horse-tail, firmly compressed by a stratum of pebbles. The trough to be replenished with water only so high that the moss and pebbles should be but slightly moistened. A cloth is to be kept over the mouth of the trough. This is imitating as near as possible their natural condition, and the charcoal not only aids in keeping the water sweet, but appears to prevent the Leeches being attacked by parasitic animals, to which they are very liable. The water should be changed about once a week, and more frequently in warm weather." To judge of the vast numbers of Leeches that are required for medical uses, and of the great importance it is to ascertain the best method of preserving them, it is only necessary to state, that four only of the principal dealers in London import between seven and eight millions annually!

THE HORSE-LEECH. (*Hirudo sanguisuga*, Linn.) The body of this species is depressed; and in the bottom of the mouth there are certain sharp tubercles. The mouth and

tail are slender; the body is pretty thick; the belly is of a yellowish green colour, and the back is dusky. It is very common in shallow pools and stagnant waters.

THE MECHANICAL LEECH. (*Hirudo geometra*, Linn.) This species is found adhering to the trout and some other fishes after the spawning season. Its motions are performed by a particular expansion of the head and tail, as if measuring like a compass; and hence it receives its name. The body is greenish, spotted with white; and both ends are dilatible and equally tenacious.

THE TUBERCULATED LEECH. (*Pontobdella muricata*.) A marine species, which adheres strongly to fish, and leaves a black impression on the place. The body, which is taper and rounded at the greater extremity, is furnished with two small horns, strongly annulated, and tuberculated on the rings; and the tail is dilatible.

LEIODON. [See SUPPLEMENT.]

LEIPOA OCELLATA. The "Native Pheasant" of the colonists of Western Australia; which in its habits is very like the domestic fowl. It deposits its eggs in a mound of sand, about three feet high, the inside being lined with layers of dried leaves,

OCCELLATED LEIPOA—(L. OCELLATA.)

grasses, &c. The bird never sits on the eggs, but leaves them to be hatched by the heat of the sun's rays. The natives are very fond of the eggs, and rob the mounds twice or thrice in a season. These mounds resemble ant-hills; and, indeed, ants often abound in them. Captain Grey observes that the nests are at least nine feet in diameter and three feet high. By the natives this bird is named *Ngowoo*.

LEMMING. (*Georychus lemmus*.) There are several species of this animal, varying in size and colour according to the regions they inhabit. They are found in Norway, Lapland, Siberia, and the northern parts of America; those of Norway being nearly the size of a water rat, and of a tawny colour, variegated with black, the sides of the head and the under parts being white; while those of Lapland and Siberia are scarcely larger than a field mouse, and much less distinctly marked. The head of the Lemming is large, short, thick, and well furred; the eyes and ears small; the body thick; and the limbs short and stout, especially the

fore legs: they have five toes on each foot, and the claws on the fore feet are strong, compressed, and rather crooked: the tail is very short, thick, cylindrical, and covered with strong hairs, disposed like those of a

LEMMING. —(GEORCHUS LEMMING.)

pencil at the tip. They subsist entirely on vegetable food. They form shallow burrows, in summer time, under the ground, and in winter make long passages under the snow in search of food. The most extraordinary characteristic of these animals is their migrations, which they undertake at irregular epochs—upon an average about once in ten years: these migrations are supposed to arise from an unusual multiplication of the animal in the mountainous parts they inhabit, together with a deficiency of food: and, perhaps, a kind of instinctive prescience of the severity of the approaching winter. They descend from the mountains in incredible numbers, and assemble in the plains; and then, as if with one consent, they march on in a direct course, no obstacle deterring them, and nothing seeming to make them turn aside. If they are disturbed while swarming over a lake or river, they will not recede, but swim on, and soon re-assume their former order. They chiefly move at night, or early in the morning; so completely devouring the herbage as they pass, that the ground has the appearance of having been burnt. Exposed as they are to every attack from owls, hawks, weasels, &c., and so many being destroyed in attempting to cross rivers and lakes, the diminution of their numbers is very great; so that comparatively very few return to their native haunts. When enraged, they raise themselves on their hind feet, and utter a barking sound. They breed several times in the year, producing five or six at a birth. Formerly, so gross was the superstition of the common people of Norway, and so great their terror at these devastating marches, that they believed the Lemmings fell from the clouds; and they were actually exorcised by the clergy.

The HUDSON'S BAY LEMMING is of an ash colour, with a tinge of tawny on the back, having a dusky stripe along its middle, and a pale line on each side. The hair is very fine, soft, and long. It is known that they migrate like the foregoing species. It occurs in Labrador, and all parts of Northern America bordering on the Polar Sea. It has the character of being very inoffensive, and so easily tamed that, when caught, it will become not only reconciled to its situation in a day or two, but show a fondness for the carcases of its master.

LEMUR. A genus of Quadrumanous animals which approximate to the Monkey tribe in having opposable thumbs on both

pairs of extremities, and to the ordinary quadruped in their elongated pointed head and sharp projecting muzzle: they are also void of that mischievous and petulant disposition which so much distinguishes the monkey tribe; and at the same time they differ from them in their dentition. They are all natives of Madagascar and of some of the smaller islands in its neighbourhood. The general form of the body is slender and elongated; the head shaped somewhat like that of a fox; and the eyes large, as in the generality of nocturnal animals. A long curved claw on the first fingers of the hind feet distinguishes them from all other quadrumanous. Their hind legs are much longer than their anterior limbs, and for the most part they are excellent leapers. Gentle and harmless as these animals in general are, they will defend themselves with great resolution when attacked. In their natural haunts they associate in troops; but they are seldom seen abroad in the day-time, always as much as possible secluding themselves from the light. They subsist on fruit, insects, and small birds. Their fur is usually very fine and silky; and the tail long and bushy: there are some species, however, which are wholly destitute of a tail, and others where that member is merely rudimentary. [See LION; for the Flying Lemur, see GALEN.]

LEO. The classical appellation for the Lion. [See LION.]

LEOPARD. (*Felis leopardus*.) A graceful and active animal belonging to the feline tribe, but so like the Panther as to be frequently taken for it by the mere casual observer. The principal difference is in size; the Leopard being considerably the smaller of the two, and of a paler yellow colour; while the ocelli or rounded marks on the Panther are larger, and more distinctly formed. Both animals are widely diffused through the tropical regions of the Old World; being natives of Africa, Persia, China, India, and many of the Indian islands. The general length of the Leopard, from

LEOPARD. (*FELIS LEOPARDUS*.)

nose to tail, is four feet; and of the tail, two and a half; and so great is its flexibility of body, that it is able to take surprising leaps, to swim, climb trees, or crawl like a snake upon the ground, with nearly equal facility. When pursued, they often take refuge in trees, and occasionally spring upon their prey from the branches. In speaking of the Leopard, Mr. Swainson observes, "Although the names of Leopard and Panther have

been long familiar in common language, and have conveyed the idea of two distinct species, yet it is perfectly clear that no scientific writer of the last generation either described, or indeed appeared to know, in what respects the animals differed. It seems that numerous specimens of what are called the Leopard are in the Zoological Gardens, and one has been figured in the book so entitled; but Mr. Bennett has not made the slightest attempt to investigate the subject, or to throw any light upon this difficult question. In this dilemma we shall therefore repose on the opinions of Major Hamilton Smith, whose long experience and accuracy of observation are well known, and whose authority in this department of nature deservedly ranks above that of any other naturalist of this country. The Leopard, as defined by Major Smith, when compared with the Jaguar and Panther of naturalists, is uniformly of a paler yellowish colour, rather smaller, and the dots rose-formed, or consisting of several dots partially "nited into a circular figure in some instances, and into a quadrangular, triangular, or other less determinate forms: there are also several single isolated black spots, which more especially occur on the outside of the limbs." Mr. Swainson then proceeds to say, "Our own opinion of the specific dissimilarity between the Leopard and the Panther, judging from what has been written on the subject, is in perfect union with that of Major Smith; while the following remark of that observing naturalist, incidentally inserted in his account of the Panther of antiquity, seems to us almost conclusive:—'The open spots which mark all the Panthers have the inner surface of the annuli or rings more fulvous (in other words darker) than the general colour of the sides, but in the Leopard no such distinction appears, nor is there room, as the small and more congregated dots are too small to admit it.' In truth, if there is any reliance to be placed in the most accurate figures hitherto published, the small spots of the Leopard and the large ones of the Panther must strike even a casual observer, and lead him to believe that the two animals were called by different names." Like most feline animals, Leopards are fierce and rapacious; and, it is remarked, that though they are ever devouring, they always appear lean and emaciated. They are taken in pitfalls, covered over with slight hurdles, on which a bait of flesh is placed. Their skins are very valuable.

THE HUNTING LEOPARD, OR CHEETAH. (*Cueparda jubata*.) This species exhibits in its form and habits a mixture of the feline and canine tribes; so much so, indeed, as to have induced some naturalists to designate it as a distinct genus under the name of *Cynailurus*, or *Cueparda*. "Intermediate in size and shape between the Leopard and the Hound," observes Mr. Bennett, in the *Tower Messenger* he is slenderer in his body, more elevated on his legs, and less flattened on the fore part of his head than the former, while he is deficient in the peculiarly graceful form, both of head and body, which characterizes

the latter. His tail is entirely that of a cat; and his limbs, although more elongated than in any other species of that group, seem

HUNTING LEOPARD.—(CUEPARDA JUBATA.)

to be better fitted for strong muscular exertion than for active and long-continued speed." Though the Hunting Leopard possesses much of the sagacity and fidelity of the dog, its anatomical structure and general habits are undoubtedly feline. The general ground-colour is a bright yellowish brown above, lighter on the sides, and nearly white beneath; marked with numerous small black spots on the back, sides, and limbs; and which are continued along the tail, so closely set as to appear like rings; the tip of the tail is white, as is also the whole of its under surface, with the exception of the rings just mentioned. The ears are short and rounded, marked with a broad black spot at the base, the tip and inside being whitish. The upper part of the head is of a deeper tinge than the rest; from each eye is a blackish line running down to the corners of the mouth, and the extremity of the nose, like that of a dog, is black. The fur does not possess that sleekness which distinguishes the feline race in general, but has a peculiar kind of crispness; and there is very little appearance of a mane, except that the hair is somewhat longer and more crisp along the back of the neck.

This useful and docile species, which it is believed might be reduced to a state of perfect domestication, inhabits the greater part both of Asia and Africa. In India and Persia, where they are employed in the chase, they are carried, chained and hoodwinked, to the field in low cars. When the hunters come within view of a herd of antelopes, the Leopard is liberated, and the game is pointed out to him: he does not, however, immediately dash forward in pursuit, but steals along cautiously till he has nearly approached the herd unseen, when with a few rapid and vigorous bounds he darts on the timid game, and strangles it almost instantaneously. Should he, however, fail in his first efforts and miss his prey, he attempts no pursuit, but returns to the call of his master, evidently disappointed, and generally almost breathless.

LEPADOGASTER. A genus of small Malacoptyrygion fishes, which have the power of attaching themselves to rocks and other hard substances, by means of the disc, whereby they are enabled to remain and find their food in situations where every

other species of fish would be swept away by the current of the water. They have large pectorals reaching to the under side of the body; head broad and depressed; snout curved and protractile; body without scales; gills with little opening, and four or five rays: they have no air-bladder, but they swim briskly.—In the Rev. David Landsborough's 'Excursions to Arran,' the little two-spotted sucker-fish, (*Lepidogaster bimaculatus*), whose fry he found on opening a scallop, furnishes him with a subject which he treats in a very pleasant and edifying manner: "How wonderfully the Lord teaches the feeblest of his creatures to provide for their own safety and that of their offspring! What a charming nursery this little sucker-fish selects for itself! It is rather nice in its choice. It is not an old, weather-beaten scallop that it takes possession of, but one that is fresh without, and smooth and pure within. After it has entered, it certainly has some way of gluing the valves together, for it is not without difficulty that they can be torn asunder. Neither is it imprisoned, though the apartment is thus shut against intruders; for, closely as the valves cohere, there are some little apertures about the ears of the shell through which it can make its exit with its numerous family, or by which such little creatures as they feed on may, in their simplicity, enter."

LEPAS. A genus of Cirrhipedous animals, of which the Barnacle (*Lepas anatifera*) is a specimen. They adhere in clusters to rocks, shells, floating wood, and other extraneous marine substances, and, being incapable of changing place, are supposed to be true hermaphrodites. The word *Lepas*, in the Linnæan system, contains all the Cirrhipeds, or Multivalves. It was formerly applied to Limpets or Patella: in short, the ancient definition, "Concilia petra adherens," would apply to any shells attached to rocks. The scientific world is much indebted to that distinguished naturalist, Charles Darwin, Esq., F.R.S., for an elaborate account of the structure, habits, and form of all the known species, which has been published in two volumes of the Ray Society's works. [See BALANUS.]

LEPIDOPTERA. An order of four-winged insects, containing some of the largest and most beautiful in nature, and comprehending all those usually ranked as Butterflies, Moths, and Sphinxes. The wings, which vary in size, figure, and position, are covered with a multitude of minute scales, which when rubbed appear like powder or farinaceous dust; the nervures of the wings being disposed chiefly in a longitudinal direction. The antennæ are composed of numerous minute joints, and are generally distinct. They are also furnished with a proboscis, composed of two sub-cylindrical tubes, between which there is an intermediate one, or sucker; and by means of it they are enabled to extract the nectar from flowers, that being the only aliment on which they subsist. The head, thorax, and abdomen are always more or less covered with hair.

In the Linnæan system, this order is composed of three genera: 1. *Papilio* (Butterflies); which in the Cuvierian system is represented by the *Diurna*; 2. *Sphinx* (the Hawk Moths); viz. the *Crepuscularia* of Cuvier, which mostly fly in the morning or evening twilight; 3. *Phalæna* (or Moths); called by Cuvier the *Nocturna*, or those which in general fly only during the night. Some of these are domestic pests, and devour cloth, wool, furs, feathers, wax, lard, flour, and the like; but by far the greatest number live wholly on vegetable food, certain kinds belong exclusively leaf-eaters, while others attack the buds, fruits, seeds, bark, pith, stems, and roots of plants. The larvæ of Lepidopterous insects are well known by the name of *Caterpillars*. [See BUTTERFLY and CATERPILLAR.]

So great is the number of insects belonging to this order, that Dr. Burmeister supposes them to amount to nearly one sixth of the whole of the insect tribes. The imago state is characterized by several peculiarities not occurring in any of the other orders. "The body is compact, and densely clothed with hairs or scales: the head is free, not being received into a frontal prothoracic cavity, but attached by a narrow ligament; it is furnished at the sides with a pair of large granulated eyes, and its hinder part often with a pair of ocelli, which are generally hidden by the thick covering of hairs or scales: the antennæ are inserted on the upper part of the head, and are generally long and multiarticulate, very variable in form, and often very complicated in the males; the mouth, at first sight, appears to consist of a long and delicate spirally convoluted organ, which, when examined, is found to consist of two pieces, each of which is sometimes provided with a small jointed appendage or palpus at its base. This very slender proboscis (or antlia as it is called by Kirby and Spence) is employed to pump up the nectar of flowers, upon which alone it subsists, into the mouth and stomach of the insect, and which, from its peculiar construction, is admirably adapted for penetrating to the depths of the narrowest blossoms. When at rest, it is coiled up, and defended by two large and compressed palpi, composed of three joints inserted upon a fleshy piece, soldered to the front of the head." * * * "The thorax is robust and compact, the prothoracic portion minute, owing to the fore-legs performing no supplemental functions, whilst the mesothorax, to which is attached the anterior pair of large wings, is greatly enlarged, the metathorax being again reduced in size. The prothorax bears upon its upper side a pair of organs, especially characteristic of the order, namely, a pair of scales covered with hair quite distinct from the wing-covers (tegulae), which Kirby and Spence call patagia or tippets, but which have been overlooked by all other authors except Chabrier, who first discovered them." * * * "The wings are attached to the lateral and superior parts of the meso- and meta-thorax, and are always present, except in a few species, of which the females alone are apterous, or have the wings reduced

to small and useless appendages; these wings are of large size, and are not folded up; the two fine layers of membrane of which the wings are composed, like the upper and lower surface of a leaf, are kept expanded by a number of longitudinal corneous veins, or nerves, as they have been called." * * * "The wings in this order offer another peculiarity, since, instead of being naked and transparent, they are clothed with a double layer of minute scales, somewhat resembling those of fishes. These scales, upon which the beauty of these insects so entirely depends, are easily detached in the form of a fine dust, and, when examined under the microscope, are exceedingly variable in their form, but generally more or less wedge-shaped, or oval; sometimes toothed or notched at the broadest end, and having a slender point at the base, by which they are attached upon the membranous surface of the wing, which, when denuded, presents the appearance of numerous minute impressions arranged in lines, in which the base of the scales are planted, being laid upon each other like the tiles on the roof of a house. The number of these scales is very great, there being more than 400,000 on the wings of the silkworm moth, according to Leuwenhoeck: In some species, however, the wings are partially, or even entirely, denuded of scales; and in others, small patches only are thus denuded, as in the great Atlas Moth. In many species, these scales exhibit the most brilliant metallic tints, so that in the bright light of the sun it is almost impossible to look upon them." * * * "The variations in the colours and markings of the wings are almost as numerous as the species themselves; the sexes also often differ materially from each other; still some general principles are evident in the distribution of these colours and markings. Thus the *Pontice* and *Pierides* are almost uniformly white; *Colias* and its allies yellow; the *Fritillaries* rich brown, spotted with black and with silvery spots on the under side; *Hipparchia* and its allies ornamented with eye-like marks; the *Lycene* copper-coloured; the *Polyommata* fine blue, with small eyes on the under side; the *Zygane* with red under wings; the *Noctuidæ* with an ear-like mark in the middle of the fore wings; the *Geometridæ* with waved carpet-like marks."—We are indebted for the previous extracts to Mr. Westwood's excellent "Introduction to the Classification of Insects." We must refer our readers, who wish to study the subject more particularly, to the works of Dr. Boisduval, Messrs. Doubleday and Hewitson, and others. The recently published Lists of British Species, drawn up with so much study and care by Mr. H. Doubleday of Epping, and by Mr. Stephens (Cat. Lep. in Brit. Mus.) are indispensable to all who study the British species; as British authors, up to his time, have been apt to multiply species, and occasionally to misapply the names, from the want of authentic specimens to compare with their species. More particular information will be found under the different species of Lepidoptera described in the course of the work.

LEPIDOSIREN. A genus placed by some authors among the Fish, by others among the Amphibia: of late it has been the subject of many learned papers, abroad and at home; the best known species is named *Lepidosiren annectens*, and is a native of Africa.

Dr. Melville differs from Professor Owen with regard to the position of this remarkable genus in the Animal Kingdom, as he regards it as a true Amphibian. He resists its character on the absence of the super-occipital bone, the presence of the large epi- and basi-cranial bones, the non-development of the maxillary and intermaxillary bones; and especially the enormous magnitude of the Wernerian bones, which become subservient to mastication, and anchored to the expanded pterygoids; on the nostril being doubled; on the existence of external cutaneous gills during the adult condition, which did not occur in any fish; and on the co-existence of external and internal gills, with lungs: in other words, on its exhibiting the different modes of circulation respiration, &c., in the produce—second stage of the larva of the frog and Amphiuma, or Menopoma, and other characters.

One species (about a foot long) inhabits the upper part of the river Gambia; and another (between two and three feet in length) is a native of the large rivers of South America. In its respiratory apparatus, it bears the closest correspondence with the Perennibranchiate Batrachia; but in many other points of its internal structure, it more resembles certain species of fishes. The African species is said to pass nine months out of the twelve in a state of torpidity; burying itself in the mud during the dry season, and again reviving when the sources of the river are swollen by the rains.

LEPIDOSTEUS. A genus of fishes with very bony polished scales, one species of which is found in the United States. Many allied genera are found in a fossil state.

LEPISMA. A Linnæan genus of Apturous insects; distinguished by an elongated body, covered with small scales, frequently silvery and brilliant. They have six feet, run with great velocity, and some of them by means of their caudal appendage are

LEPISMA VITTATA.

enabled to leap. The antennæ are setaceous, and usually very long. Several species hide beneath stones; others conceal themselves in the cracks of old window-frames and under damp boards, &c.

LEPTIDÆ. A subfamily of Dipterous insects, distinguished by the proboscis being short and membranous; the lps terminal and thick; and the abdomen usually with five distinct segments.

LEPTOCEPHALUS, or ANGLESEA MORRIS. A Malacoptyergious fish, characterized by a very small and short head, and a remarkably compressed body. It is common in the seas of hot climates. One specimen of it was taken on the coast of Anglesea by a gentleman named Morris, and is described by Pennant; but since that time many others have been found on our coasts. It is four inches long; head very small; the eyes large; lower jaw slender; numerous small teeth in each jaw; the body compressed sideways; extremely thin, and almost transparent: the bones forming the vertebrae have no spinous processes whatever; the dorsal and abdominal margins, as well as the lateral line, exhibit a series of small black specks; and its general opal-like hue and graceful motions give it a very pleasing appearance. It is usually found among sea-weed.

LEPTOCONCHUS. A genus of Mollusca, found in the Red Sea, where it is imbedded in calcareous masses of Polyperia. The head of the animal is furnished with a proboscis; two tentacula, with eyes in the middle; foot of moderate size, and no operculum. The shells is of a dirty-white colour, subglobular, delicate, fragile, and translucent; spire low; aperture large, and furrowed externally.

LEPTOPIHNA. The name given to a subfamily of serpents belonging to the family Colubridæ. They are characterized by a long and very slender body, slightly depressed: the head elongated, and narrowed before; and a very long, slender, and acutely pointed tail. "The whole of the serpents composing these genera live," Mr. Bell observes, "in woods, entwining themselves amongst the branches, and gliding from one to another. Their habits, combined with the graceful slenderness of their form, the beautiful metallic reflection from the surface in some species, and the bright and changeable hues in others, place them among the most interesting of the serpent tribe. Their food consists of large insects, young birds, &c., which the extraordinary size of the head, the width of the gape, and the great dilatibility of the neck and body, enable them to swallow, notwithstanding the small size of these parts in a state of rest." They are perfectly harmless; and it is even said that children are in the habit of taming and playing with some of the species, and the snakes appear pleased at being thus caressed.

LEPTOPLEURON. [See SUPPLEMENT.]

LEPTOPTILUS. A genus of Gallatorial birds, containing the well known *Adjutant* of India [which see].

LEPTURIDÆ. The third family of Longicorn beetles, comprising such as have

the eyes rounded, or very slightly emarginate; the antennæ of moderate length inserted before the eyes; the head is inclined downwards, and narrowed into a neck at its union with the thorax, which is conical or trapezoid, and narrower in front than the head; the mandibles are acute at the tips; the elytra are narrowed to the tips, so as to give the terminal part of the body the appearance of an elongated but reversed triangle. These insects are of moderate size, active, and generally gaily coloured, being often ornamented with yellow markings; they are found either upon umbelliferous flowers in the hot sunshine, or on the trunks of trees, where they usually reside in their previous states.

One of the largest and finest of these beetles is a North American species, the *Desmocerus palliatus*, which appears on the flowers and leaves of the common elder towards the end of June and until the middle of July. It is of a deep violet or Prussian blue colour, sometimes glossed with green, and nearly one half of the fore part of the wing-covers is orange-yellow, suggesting the idea of a short cloak of this colour thrown over the shoulders, which the name *palliatus*, that is, cloaked, was designed to express. The head is narrow; the thorax is narrow before and wide behind, and has a little sharp projecting point on each side of the base. The larvæ live in the lower part of the stems of the elder, and devour the pith, as Dr. Harris informs us. In this country are many species, some of which are rather large and handsome. They are described in the works of Mr. Stephens.

LEPUS. [See HARE.]

LERNEADÆ. A group of parasitic crustacea; one species of which infests the Sun-fish (*Orthopristis*). The fish and its parasite are thus described in Capt. Grey's Travels in Australia: "We caught also a fish (*Orthopristis*), which the seamen called a devil-fish. The length of it was six feet two inches; breadth from fin to fin, three feet six inches; length from tip of nose to pectoral fin, two feet; thickness through the breast, one foot six inches. This fish was infested about its nose with a kind of parasite (*Lernæa*), having two long thin tails. The sailors stated that these animals frequently cause large sores about the nose of the fish, and that when suffering from this, it will allow the sea birds to sit on it, and peck away at the affected part. The habit of the fish is to swim during calms, with one of the hind fins out of water, and it is then harpooned from a boat. I have myself seen petrels perched upon them; and directly one of these fish was hoisted on board, the sailors looked for the parasites and found them. They were an inch long, and covered with a transparent shell marked with gray spots and lines; the hind part of the body, near the tail, being darker than the fore part, as if the intestines were seated there. These little creatures adhered strongly to any substance that they were laid on, and caused an irritating feeling to the skin, if placed on it; they swam with great rapidity when put

into sea water, and in their movements in swimming much resembled a tadpole; their tails were merely long transparent fibres."

ANTHOSOMA SMITHII

Our figure represents a species, *Anthosoma Smithii*, which derives its generic name from its body resembling the blossom of a flower. In Dr. Baird's British Entomostraca figures and descriptions of the British species are given.

LESTRIS. A genus of Palmipede birds, distinguished from the true Gulls by their membranous nostrils being larger and opening nearer to the point and edge of the beak; the tail also is pointed. The females are larger than the males, which is the reverse of what is observable in the genus *Larus*; and they lay but two eggs, of a dark colour.

LESTRIS PARASITICUS; the ARCTIC GULL. This species is common in the northern parts of Europe, Asia, and America. Numbers of them frequent the Hebrides in the breeding season; and they are also to be seen in the Orkneys, and on the coast of Yorkshire. They make their nest of moss, on the dry grassy tufts in boggy places, and lay two eggs of an ash colour, spotted with black. The length of the Arctic Gull is twenty-one inches: the bill is dusky, pretty much hooked at the end, but the straight part is covered with a sort of cere: the nostrils are narrow, and placed near the end. In the male the crown of the head is black; the back, wings, and tail are dusky; and the whole under side of the body is white: the legs are small, scaly, and black. The female is entirely brown. They are ravenous and ferocious to such a degree, that they pursue other gulls of a less vigorous and determined nature, whenever they observe them to have a prize worth contending for, and compel them to drop or disgorge their prey; which the pursuer usually catches as it falls. Mr. Fisher, in his Journal of a Voyage to the Arctic regions, in H. M. S. *Hecla* and *Griper* (1820), gives the following information on this subject: "Several Arctic Gulls were seen to-day for the first time. This bird is commonly called by our Greenland seamen the Boatswain, and sometimes Dirty Allen, a name somewhat analogous to that by which it is characterized by the Danes, viz. *Stroudt-jager*, or *Dung-bird*. All these names have had their origin from a mistaken notion that these birds lived on the excrements of the lesser gulls, which, on being pursued, either from fear, or to relieve themselves from the persecution of fierce enemies, voided something to satiate the voracious appetites of their pursuers, and by that means escape from further molestation. The fallacy of this opinion is now, however, pretty generally known. That the Arctic Gulls do pursue those of their own genus which they can master (particularly the Kittiwakes) is an incontestable fact; but the object of their

pursuit is not the excrement, but the prey that the pursued is at that time possessed of, and which at length they are forced to drop, to secure their own safety; which they effect during the time that their enemy is employed picking it up, although that is done in a very short period, for they manage the business with such dexterity, that the object dropped is generally caught before it reaches the water."

LESTRIS CATARACTES; the SKUA GULL. This is the most formidable of all the Gull kind, preying not only on fishes, but also on the smaller kinds of water-fowl, and, as some assert, even on young lambs. It is a stout bird, two feet in length, and between four and five from tip to tip of the extended wings. The bill is dark, strong, much hooked, sharp at the tip, and covered to the nostrils with a kind of cere. The whole upper plumage is of a deep brown, edged with a dull rust colour; the under parts being considerably lighter: the tail is white at the root, the shafts are of the same colour, and the webs of deep brown: the legs and toes are covered with coarse black scales; and the claws are strong and hooked. This fierce species is met with in the high latitudes of both hemispheres, where they are much more common than in the warm or temperate parts of the globe. They are uncommonly courageous in defence of their young, and attack, with eagle-like courage and ferocity, any animal that dares to disturb them; nay, those persons who are about to rob their nests, aware of the reception they are likely to meet with, hold a knife or other sharp instrument over their heads, upon which the enraged bird rushes, to its own destruction. By many people their feathers are preferred to those of the goose; and in some parts they are killed in great numbers merely for the sake of them.

LEUCISCUS. A genus of Malacopterygious fishes, of the genus *Cyprinidae*. It contains many species, chiefly distinguished from others of the Carp tribe by the comparative shortness of the dorsal and anal fins, and a deficiency of barbules about the mouth. [For examples of this genus, see BLEAK: CHUB: DACE: ROACH, &c.]

LEUCOPHASIA; called by Hübner *Lep-toria*. A genus of Butterflies distinguished from the other "*Whites*" by the narrow elongated wings, rounded at the end. There are few species in this genus; we particularize the British

LEUCOPHASIA SINAPIS; or WOOD WHITE BUTTERFLY. In certain woods and copses this insect is to be met with at the end of

WOOD WHITE BUTTERFLY.
(LEUCOPHASIA SINAPIS.)

May and beginning of August. Its wings above are milk-white, with a dusky rounded spot at the tip of the anterior, and the base sprinkled with dusky ; beneath, the tip and base are yellowish tipped with green : the posterior wings are faintly tinged with yellow and sprinkled with dusky clouds ; body cinereous above, white beneath ; antennæ white, with black rings. In the female the wings are more rounded. Caterpillar green, with a deep yellow lateral line : it feeds on the *lotus corniculatus*. The *Chrysalis* is fusiform, greenish with a yellow streak on the sides, and white spots on the stigmata.
